Glomangioma of the lungs: a rare differential diagnosis of a pulmonary tumour

Glomangiomas (gliom tumours) are uncommon, and in most cases are benign perivascular tumours, usually located in the dermis of the extremities, especially in the subungual region of the fingers. They also occur in other organs and in other regions of the body. Histogenetically, they are derived from modified smooth muscle cells of the glomus apparatus, which is associated with temperature regulation. These tumours are composed of capillaries, sometimes of dilated endothelial bigger vessels surrounded by nests of uniform, cytoplasm-rich cells with isomorphic round or ovoid nuclei (glomus cells). They also contain a variable amount of smooth muscle tissue. Three different types of glomus tumours are described according to their different components. The common form is predominantly made up of glomus cells, with a smaller amount of vessels and smooth muscle cells. The second variant, called “glomangioma”, contains more partly dilated vessels resembling cavernous haemangiomas and is less circumscribed than the common form. In the most rare type, the “glomangiomyoma”, the glomus cells undergo a transition to elongated smooth muscle cells.

Immunohistochemically, glomus tumours usually show a positivity for vimentin and smooth muscle actin and a negativity for cytokeratin, neuroendocrine markers (chromogranin and others), CD31, CD34 and S-100. These tumours are very rare in the lungs, and, to our knowledge, only 14 cases have been described, including two malignant glomus tumours.

Case report

A 64-year-old man was admitted to the hospital for resection of a carcinoma of the rectum. The preoperative computed tomography showed a round tumour (3.3 cm) in the left lower lung lobe that was removed 2 weeks after the resection of the rectum.

Findings

On macroscopic examination, the round tumour was reddish. Histological examination (haematoxylin and eosin, Elastica-van-Gieson, Prussian Blue and periodic-acid Schiff) showed lung tissue with partly compressed, partly hyperaemic and ectatic vessels that exceeded the normal density of alveolar capillaries (fig 1A,B). Cytoplasm-rich cells with round isomorphic nuclei were arranged diffusely perivascularly and in nests. Immunohistologically, the tumour cells featured a cytoplasmatic staining for $\alpha$-smooth muscle actin (fig 1A), whereas the reactions with antibodies against CD31, CD34, pancytokeratin and TTF-1 were negative.

Comment

On the basis of the histological and immunohistological results, a metastasis of the rectal carcinoma was ruled out and the tumour was identified as a glomangioma of the lung.

The other important differential diagnoses, including carcinoid small-cell lung cancer, melanocytic neoplasms, haemangiopericytoma, smooth muscle neoplasms, paragangioma and primitive neuroectodermal tumours, were also excluded by morphology and immunostaining pattern.
