

Cortisol and 17-Hydroxyprogesterone Levels in Saliva of Healthy Neonates

Normative Data and Relation to Body Mass Index, Arterial Cord Blood pH and Time of Sampling after Birth

Cortisol · 17-Hydroxyprogesterone · Neonate · Neonatal stress · Saliva · Circadian rhythm

Abstract

The measurement of cortisol and 17-hydroxyprogesterone (17-OHP) in saliva has become a reliable tool for both the scientist and the clinician for studying adrenal cortical function in the adult and the older child. We have now established in parallel normative data for salivary cortisol and 17-OHP levels in healthy neonates. We have asked whether or not there is a circadian rhythm of cortisol and 17-OHP saliva levels in neonates. Furthermore, we have asked whether salivary hormone levels correlated with auxologic and clinical data and time of sampling. Cortisol and 17-OHP levels in saliva samples from 119 healthy neonates (55 girls, 64 boys) were measured using in-house time-resolved fluorescent immunoassays. Saliva samples were obtained using a saliva collecting tube three times a day on the first or second day of life. Gender and gestational age did not influence salivary cortisol and 17-OHP levels. No significant circadian

rhythm of salivary hormone levels was detected in this group of newborns. However, body mass index, arterial cord blood pH and time of saliva sampling significantly influenced salivary hormone levels. In conclusion, measurement of cortisol and 17-OHP in saliva is feasible in healthy neonates. The existence of normative data forms the basis for future studies on pathophysiological states in the newborn period.

Introduction

Corticosteroids are essential for the development of the fetus. In early neonatal life, cortisol is already of importance for stress responses and metabolic homeostasis. The concentration of cortisol in amniotic fluid increases during gestation towards a maximum at 38–40 weeks of gestation with levels of 82 ± 12 ng/ml [1, 2].

The 17-hydroxyprogesterone (17-OHP) levels in amniotic fluid in early gestation (1.63 ± 0.21 ng/ml, mean \pm SD) are also significantly lower than the levels found later in gestation. From the 36th to the 38th week of gestational

age, 17-OHP levels reach a maximum of 3.8 ± 0.74 ng/ml [3]. High 17-OHP levels in amniotic fluid are found in fetuses with congenital adrenal hyperplasia [4, 5].

The transplacental transfer of cortisol and synthetic glucocorticoids has been demonstrated. In the middle of gestation, maternal plasma cortisol levels are 8–10 times higher than the fetal concentrations [6, 7]. The relative biologic activity and metabolic rates of glucocorticoids during gestation and at term have been studied previously [8–11].

The measurement of cortisol and 17-OHP in saliva has become a reliable tool for both the scientist and the clinician for studying adrenal cortical function in the adult and the older child [12–15]. We have now established in parallel normative data for salivary cortisol and 17-OHP levels in healthy neonates. In addition, we have asked whether or not there is a circadian rhythm of cortisol and 17-OHP saliva levels in neonates and whether salivary hormone levels correlate with clinical data of the newborns and time of sampling. Cortisol and 17-OHP levels in saliva samples from 119 healthy neonates were measured using in-house time-resolved fluorescent immunoassays. These normative data are expected to build the basis for future studies on pathophysiologic states of adrenal function and stress responses in the newborn period.

Subjects and Methods

Subjects

Saliva cortisol and 17-OHP levels were determined in 119 healthy neonates (55 girls and 64 boys). Auxologic and clinical data were recorded using a structured questionnaire (table 1). 25 neonates were born by sectio caesarea, 94 vaginally. Duration of birth was 44–54 min and the time from onset of labor until birth was 414 ± 256 min in the 94 neonates with vaginal delivery. Saliva was collected 18–24 h (n = 21) or 25–55 h (n = 98) after birth.

Saliva Sampling

From each infant, three saliva samples were taken at 7:00, 13:00 and 19:00 h before meals. Saliva was obtained by using a saliva collecting tube with a cotton swab inside (Salivette®, Sarstedt, Nümbrecht, Germany). The cotton swab was left in the neonates' mouth for 5 min. This procedure did not cause any distress. Saliva samples were centrifuged and stored frozen at -20°C until analysis.

Cortisol and 17-OHP Assays

Samples were analyzed using in-house time-resolved fluorescent immunoassays as described before [12, 13]. In some cases, sample volumes were too small for duplicate determination of the two hormones. Therefore, some measures contain smaller sample numbers (<119). In brief, specific polyclonal antibodies against cortisol and 17-OHP respectively were used as first antibodies. Cortisol or 17-OHP biotin conjugates were used as tracers. Cross-reactivities of the

Table 1. Anthropometric and clinical data of the 119 healthy neonates investigated in respect to salivary cortisol and 17-OHP levels

	Median	Range
Gestational age, weeks	39	31–42
Weight, g	3,290	2,080–4,550
Length, cm	51	45–57
Head circumference, cm	34	30–38
Body surface, m ²	0.2	0.15–0.25
BMI, kg/m ²	12.5	9.8–15.9
Cord blood pH	7.31	7.07–7.53

immunoassays were very low [12, 13]. Hence, the assays are considered to be ideal for measuring steroid levels in the neonatal period. The interassay coefficient of variation was between 4.1 and 11.7% for the cortisol assay and between 5.0 and 9.8% for the 17-OHP assay. The intraassay coefficient of variation was between 5.3 and 8.8% for the cortisol assay and between 5.0 and 9.8% for the 17-OHP assay.

Results

Anthropometric and Clinical Data

Anthropometric and clinical data of the neonates are summarized in Subjects and Methods and in table 1. As was expected, there was a correlation between gestational age and auxologic parameters (data not shown).

Cortisol and 17-OHP Levels in 119 Healthy Neonates

Cortisol and 17-OHP levels were measurable in saliva samples of all healthy neonates. Only on rare occasions was there too small a saliva volume to measure both hormones in duplicate. There were no differences between cortisol and 17-OHP levels in saliva from male and female neonates (data not shown). Normative data for salivary cortisol and 17-OHP levels in the neonatal period were generated (table 2, 3). Interestingly, there was a significant difference in salivary hormone levels when time of sampling was analyzed: significantly higher morning cortisol levels ($p = 0.015$) were found in the group in which samples had been taken 18–24 h after birth compared to the group where samples had been obtained 25–55 h after birth (fig. 1a). 17-OHP levels were significantly higher at all three times (morning $p = 0.001$, midday $p = 0.017$, evening $p = 0.038$) in the group where saliva samples had been taken 18–24 h after birth compared to the group where samples had been taken 25–55 h after delivery (fig. 1b).

Fig. 1. Salivary cortisol (**a**) and 17-OHP levels (**b**) (median, 1st and 3rd quartile) in 119 healthy neonates with samples taken 18–24 (\diamond) or 25–55 (\times) h after birth as described in Methods. In the group in which saliva samples were taken within 24 h after birth, morning, midday and evening 17-OHP and cortisol levels were significantly higher (morning $p = 0.001$, midday $p = 0.017$, evening $p = 0.04$ for 17-OHP; morning $p = 0.0015$ for cortisol) compared to the group in which samples were obtained later than 24 h after birth.

Evening	247.1 \pm 131.4	92.3–739.2	205.6	56

Lack of Circadian Rhythm of Cortisol and 17-OHP Levels

Neither saliva cortisol levels nor 17-OHP levels showed a circadian rhythm (fig. 1a, b). However, there was a significant correlation between 17-OHP levels in the morning, midday and evening (morning and midday $r = 0.7$, midday and evening $r = 0.67$, morning and evening $r = 0.63$).

Salivary Cortisol Levels as an Indicator of Stress in the Neonate

Arterial cord blood pH values were significantly and inversely related to the duration of labor in the whole group of neonates considered to be healthy and not exposed to known unexpected stresses ($r = 0.37$, $p >$

0.001 ; data not shown). When we asked whether or not early cortisol levels were related to cord blood pH as an indicator of stress to the baby, a significant inverse relation was found in the group of infants where saliva samples had been taken within 24 h after birth ($r = -0.52$).

Relation between Cortisol and 17-OHP Levels in Saliva

Since both cortisol and 17-OHP can be derived from the adrenal cortex of the infant, we have asked whether or not cortisol and 17-OHP levels in saliva of healthy neonates correlated. In fact, when parallel measurements of cortisol and 17-OHP in a total of 240 saliva samples were analyzed, there was a significant correlation between cortisol and 17-OHP levels in saliva ($r = 0.33$, $p < 0.0001$).

Discussion

Significantly higher salivary cortisol levels (mean 14.25 ng/ml) were found in infants in which saliva had been sampled within the first 24 h after birth compared to the group of infants in which samples had been obtained 25–55 h after birth (mean 9.76 ng/ml; $p < 0.001$). We hypothesize that stress might contribute to high cortisol production of the neonate around birth and during delivery [15, 16]. As a consequence, high cortisol saliva levels are present at birth and shortly thereafter. Due to the short half-life of cortisol, the high cortisol levels then decline rapidly during the first days of life. This assumption is in agreement with the findings of Bertrand et al. [14] who also found that cortisol levels declined after birth. They also investigated plasma cortisol levels of 75 neonates born at term. Maximum cortisol levels (40.5 ng/ml) were found shortly after birth, while a minimum (6.7 ng/ml) was observed between the 3rd and the 5th day of life. These data are in accordance with our data in respect to saliva cortisol levels. In addition, Bespalova et al. [15] showed a decline in plasma cortisol levels within the first day of life in healthy neonates. Kurihara et al. [17] investigated saliva and plasma cortisol levels as an indicator of stress in neonates. Saliva cortisol levels showed a close correlation with plasma cortisol levels. Cortisol levels were positively related to stress in this group of neonates and infants.

In our study, low cord blood pH was related to longer duration of labor ($r = 0.26$, $p = 0.01$). It has to be emphasized in this context that all infants studied by us were healthy, not asphyxiated and undistressed. Therefore the range of cord blood pH values is limited. It would be expected that in a study also involving ill or distressed neonates, a larger range of pH values would be found. Still there was a striking inverse relation between morning cortisol levels and cord blood pH ($r = -0.52$, $p = 0.017$) in the group in which samples were taken within 24 h after birth. In the same group, there was a positive correlation between morning cortisol levels and body mass index ($r = 0.58$, $p = 0.006$). A multiple regression analysis showed that both correlations just exist because of two extremely high morning cortisol levels, which belong to two participants with extremely high body mass indices. We hypothesize that elevated salivary cortisol levels – as an expression of increased stress – might be related to high body mass index and near asphyxiation. This hypothesis should be tested in a prospective study involving distressed and asphyxiated as well as healthy neonates.

It is unclear at what time of infancy the circadian rhythmicity of cortisol release is first present. Some authors believe that rhythmicity starts as early as within the 2nd week of life [15, 18–23], while others state that the circadian rhythm of cortisol plasma levels is only present after 9 months of life [16]. In our study, no circadian rhythmicity was present in the whole group of 119 infants during the two days of the study period.

Reference values of plasma 17-OHP levels in neonates and infants have been reported previously [24, 25]. We now provide normative data on 17-OHP saliva levels in neonates. In our study, 17-OHP salivary levels rapidly decreased from the first to the second day of life. This finding goes along with the data from Sippell et al. [20] who showed that 17-OHP blood levels decrease rapidly after birth [20, 25]. In contrast to salivary cortisol levels, 17-OHP morning, midday and evening levels show a remarkable correlation: high morning levels are related to high midday and high evening levels. As a result of this, it could indeed be possible to take just one sample a day in order to, e.g. screen for congenital adrenal hyperplasia using saliva samples.

In conclusion, we have established normative data for salivary cortisol and 17-OHP in healthy neonates (table 2, 3; fig. 1). The salivary concentrations of both hormones decline rapidly after birth. No gender difference of salivary cortisol and 17-OHP levels was found. The determination of salivary cortisol levels in neonates might be a helpful measure to control for neonatal stress and birth asphyxia.

Acknowledgments

We wish to thank Christian Smit for helping collect samples. We also wish to express our sincere gratitude to the parents who gave permission to study their infants. We gratefully acknowledge the generous gift of saliva collecting devices (Salivette®) by Sarstedt, Nümbrecht, Germany.
