\section*{Introduction}

Preeclampsia is a common syndrome and remains a major cause of maternal and fetal morbidity and mortality [1, 2]. Most women develop the late-onset syndrome with normal fetal growth, whereas a smaller subset develops the early-onset syndrome usually accompanied by intrauterine growth restriction (IUGR) [3, 4]. Both types of the syndrome are characterized by systemic inflammation that resolves following delivery. Since trophoblast fragments and proteins, microvillous membranes and cell-free fetal DNA are all detectable in higher amounts in maternal blood of preeclamptic women, the placenta is the likely source of this inflammatory disorder [3].

The prevention of preeclampsia remains a considerable challenge in obstetrics. Neither low-dose aspirin [5] nor antioxidant vitamins [6, 7] were shown to be helpful in preventing any type (early- or late-onset) of preeclampsia. One reason why preventive strategies for this syndrome have proven so disappointing at present is that the proposed interventions have commenced in the mid to late second trimester, when the underlying placental disorder triggering the syndrome may already be established. Thus, novel biomarkers of the syndrome expressed in early pregnancy and suggest syncytiotrophoblast necrosis.
Recently, the concentrations of placental protein 13 (PP13) [8] were shown to be altered in maternal blood in pregnancy disorders such as preeclampsia [9]. More recent studies have shown that the serum levels of PP13 are significantly reduced at 11 to 13 ± 6 weeks in cases developing early- as well as late-onset preeclampsia [10, 11]. On the background of these data, we analyzed cases developing late-onset preeclampsia longitudinally throughout their pregnancies. PP13 is expressed in the placental syncytiotrophoblast, and its levels in maternal blood may reflect turnover and integrity of this layer. Our data suggest a biphasic alteration in maternal expression of PP13 during the evolution of pregnancies that ultimately develop preeclampsia.

Materials and Methods

Study Design and Population
The prospective study involved the Women's Hospital at the University of Zurich, Switzerland and a collective of doctors in private practice at Nordhorn, Germany. The study was approved by the ethical committees of both centers and women were enrolled after providing informed consent. Patients were followed from the first positive β-hCG test at enrolment throughout antenatal visits during pregnancy until delivery, and outcome was documented in the early postpartum period. Five-milliliter aliquots of blood were provided every 2–4 weeks from enrolment until 5–15 weeks after delivery. Serum was stored frozen at −70°C until tested. Demography, maternal medical history, results of blood pressure measurements, urinalyses and laboratory tests were collected and recorded within an electronic database, as were the later pregnancy outcomes (Table 1).

Women aged 18–45 years with a singleton gestation who delivered after 20 weeks were included in the current study. The total number of patients enrolled was 92, of which 19 were excluded due to missed abortions or incompatibility (no blood or loss of follow-up). Ten patients with multiple admissions of tocolytic agents were excluded due to tocolytic effects on PP13 serum levels discovered post factum, which will be reported elsewhere [Huppertz, pers. commun.]. Accordingly, the current report describes the results obtained from 63 patients, 4 of them preeclamptic and 59 unaffected. The 4 patients who developed preeclampsia correspond to 4.5%, as expected from previous epidemiological results [9, 10]. Optical density was measured at 450 nm against a 650-nm background and translated to a quantitative amount by using a calibration curve made of recombinant PP13 standards (0–500 pg/ml). The assay’s operating range is 5–400 pg/ml, and samples with lower readings were assigned the value 5 pg/ml. The intra- and interassay coefficients of variation for this study were 5.3 and 9.5%, respectively, while the recovery coefficient of variation was 11.5%.

Statistical Analysis
Baseline and delivery characteristics were compared between cases and controls using the Fisher exact test for categorical variables and independent t tests for continuous variables.

PP13 levels were not normally distributed; therefore, we compared PP13 levels across the 2 outcome groups using the Wilcoxon rank sum test. PP13 levels increased with gestational age. To take this effect into account, PP13 levels were converted to multiples of the normal median (MoM) for the controls at the same gestational age, based on a weighted (by number of cases) regression of the observed median at each completed week. We examined other major confounders: PP13 did not change with body mass index (p = 0.168), age (p = 0.737), parity (p = 0.147) and ethnicity (p = 0.606). Thus, the calculation of MoM was not further adjusted to these confounders.

Immunohistochemistry
Term placentas from normal (n = 5) and late-onset preeclampsia (n = 5) cases were obtained from the Women’s Hospital of Aachen University, Germany and the Wolfson Medical Centre in Holon, Israel at the time of this study after obtaining informed consent and the placentas were then used for immunohistochemistry. These 10 cases were not related to the cases tested for serum PP13.

A tissue block of each placenta was fixed in 4% formaldehyde, dehydrated in a graded series of ethanol and embedded in paraffin. Five-micrometer sections were cut, mounted on glass slides and deparaffinized. Immunohistochemical staining was performed with monoclonal primary antibodies against PP13 (monoclonal antibodies 27-2-3 and 215-28-3) at a dilution of 1:10. Positive staining appeared red after using a standardized staining sequence based on the horseradish peroxidase-linked streptavidin-biotin technique for the detection of a biotinylated secondary antibody and AEC detection reagent. Control reactions excluded the use of primary antibodies or made use of a negative control antibody (DAK-GO1; Dako) and were always negative.

Results

Demography and Delivery Characteristics
Table 1 displays the baseline and delivery characteristics in relation to pregnancy outcome. Women were of...
similar age at enrolment (31 ± 5, 33 ± 7 and 30 ± 4 years for normal control, unaffected and preeclamptic women, respectively) and were enrolled at a similar gestational age (7.8 ± 2.2, 6.8 ± 2.7 and 9.1 ± 2.1 weeks, respectively). About 60% of the enrollees were Caucasian in either group. The preeclamptic and normal outcome group women delivered at term; delivery of the unaffected group was lower due to the patients who delivered preterm (35.2 ± 1.4 weeks). All preeclamptic patients delivered by vaginal delivery (80% in the normal outcome group and 70% in the unaffected group in which 6/8 preterm cases and 4/10 short cervix cases delivered by caesarean section). Baby birth weight was similar in the control group (3,446 ± 417 g) compared to the preeclamptic group (3,300 ± 728 g), but lower in the unaffected group (3,017 ± 547 g) due to the preterm delivery cases (2,100 ± 330 g).

At enrolment, all patients had normal blood pressure and none or traces of proteinuria. At 35 ± 3 weeks, both systolic and diastolic blood pressure of preeclamptic patients were elevated above 140/90 with proteinuria of 2+ (95% CI: 2+ to 4+).

**PP13 Blood Levels**

Following each individual patient with normal outcome, it was discovered that their values did not change much during the first trimester, although fluctuations around the median values indicated a tendency towards higher values near the time that pregnancy was established by the β-hCG test and at the end of the first trimester (fig. 1a, solid line). For each individual patient, the values were on average 25% higher in the second trimester and approximately double this amount towards term at around 35–36 weeks. At 8–12 weeks after delivery (corresponding to 41–45 and 46–50 weeks from the last menstrual period), PP13 disappeared from the maternal serum (fig. 1a, solid line), thus enabling us to use this as a baseline to correct the values of each individual woman. This approach improved the accuracy of the analysis.

To obtain the cross-section of the 41 normal patients (430 blood samples), median PP13 values with 95% CI were calculated (table 2). Median first trimester PP13 level adjusted to gestational week after weighted (by number of patients) regression was 166 pg/ml (range 126–202). The median second trimester level adjusted to gestational age was 202 pg/ml (range 171–233), reflecting an average increase of 25% between the first and the second trimester. Values for individuals increased 50–100% from the first trimester to the maximum value reached during the third trimester. PP13 disappeared from maternal blood after delivery, indicating that serum PP13 is directly related to pregnancy and the presence of the placenta (table 2; fig. 1a, solid line).

Comparison of the normal group to the total unaffected group [including cases that subsequently delivered preterm or those with a relatively shorter cervix (fig. 1a, triangles)] indicated that the normal and unaffected women almost overlap and the differences were not significant throughout pregnancy (table 2).

In contrast to the above, the level of PP13 in preeclampsia cases (51 blood samples collected from 4 patients) started lower than normal (fig. 1a, dashed line).

PE = Late-onset preeclampsia; GA = gestational age.
Although differences between individuals occurred, all individuals had very low PP13 values during the period of gestational age 5–15 weeks with median values of 35 and 46 pg/ml for gestational age 5–10 and 11–15 weeks, respectively, with p < 0.001 and 0.01, respectively, compared to normal cases of the corresponding gestational age (table 2; fig. 1a, dashed line). The standard deviation in this group was very small. In fact, for the very early...
time point of 7 weeks, there was no overlap between the individuals of the 2 groups and all normal cases were higher than preeclamptic patients. During the second trimester, the PP13 values in the preeclampsia cases grew to reach normal levels with medians at gestational age 16–20, 21–25 and 26–30 weeks growing to 147, 265 and 367 pg/ml, respectively (p < 0.04, 0.21 and 0.75, respectively; table 2). During the third trimester, PP13 values of the preeclamptic patients overshoot above normal with medians at gestational age 31–35 and 36–40 weeks reaching 539 and 894 pg/ml, respectively (p = 0.05 and 0.001, respectively; table 2). In the preeclampsia group, PP13 was elevated 7–15 times for each individual patient between the first and the third trimester, whereas average differences for the women of the normal outcome group were 1.4–2 times. After delivery, the values decreased back to normal and then completely disappeared, indicating that serum PP13 is directly related to pregnancy and placenta (table 2; fig. 1a).

PP13 MoM

Based on medians at each gestational age of the normal outcome group, the corresponding MoM value was set to 1.0. For the late-onset preeclampsia group, the PP13 MoM values were significantly lower than in the normal group at gestational age 5–10 and 11–15 weeks (table 2). During the second trimester, MoM values were growing towards the normal level (table 2). Third-trimester values reached above normal and became significantly different again (table 2) when symptoms of preeclampsia were clinically evident. The change of MoM values for any preeclampsia patient during the entire period reflected initial low MoM values at the period of risk assessment, growing gradually into very high MoM values during the outbreak of clinical symptoms of the pathology. After delivery, PP13 disappeared from the blood in all cases and controls. Values for the unaffected group were slightly but not significantly lower compared to the normal group (table 2).

Immunohistochemistry

Immunohistochemical staining for PP13 in human term placentas revealed a clear and nearly exclusive staining of the apical membrane of the syncytiotrophoblast (fig. 2a). With this staining, also the microvillous brush border became visible. In cases from late-onset preeclampsia, staining for PP13 revealed a similar picture (fig. 2b–d). Here, increased staining of the apical syncytiot membrane was found and additional staining of fetal blood vessels was present (fig. 2b, asterisk). In the pathological cases, alterations of the apical membrane became obvious, displaying structures that may lead to the necrotic release of syncytiotrophoblast membrane fragments, known to be increased in preeclampsia [15].

Discussion

Limitations

This study was carried out with a relatively small cohort and compares 4 term preeclampsia cases with 59 unaffected cases (41 with normal outcome). While the proportion of cases fits the size of the cohort, the discussion takes into consideration that this is an initial observation that should stimulate the implementation of a larger cohort study. The limited number of cases is slightly misleading, since the longitudinal sampling of 10–12 blood samples from each participant enabled us to gain a quite reliable view on the change over time for
Correlation between PPI3 Concentrations and Normal Development of the Placenta

Following the concentrations of PPI3 in maternal peripheral venous serum, there is a slight reduction around the time of onset of maternal blood flow into the placenta, that is, between weeks 9 and 13 [16]. After the establishment of maternal blood flow through the placenta, there is a constant increase in PPI3 in maternal blood until near term. It peaks at around 36 weeks and then slightly decreases until delivery. Afterwards, it disappears within a week. Figure 1b shows the course of PPI3 throughout pregnancy in control women (same data as in fig. 1a, solid line) related to the course of other placental parameters that change during pregnancy: trophoblast volume and villous surface (data taken from Mayhew and Barker [17]). It becomes obvious that all 3 courses display the lowest values at the transition from the first to the second trimester followed by a constant increase starting at around midgestation. Since PPI3 is expressed in the syncytiotrophoblast outer membrane, it is tempting to speculate that the increase in PPI3 nicely reflects the increase in villous surface extension during pregnancy. Any disturbance of the villous surface in terms of surface area or surface integrity will have a direct impact on the amount of PPI3 released into the maternal circulation.

Assessing Abnormal Placental Development Already in the First Trimester of Pregnancy and Allowing to Test Putative Preventive Therapeutic Interventions

The longitudinal measurements of PPI3 throughout pregnancy provide a clear picture of the changes in PPI3 release in cases with late-onset preeclampsia. They start with a significantly lower release during the first trimester, cross the normal course at about 20 weeks and peak prior and during the time of clinical symptoms. With these characteristics, the release of PPI3 is well suited to distinguish normal pregnancy from cases developing late-onset preeclampsia already during or at the end of the first trimester. This of course will be ameliorated if other factors will be evaluated in parallel as has been done for trisomy 21 [18].

Recently, 2 studies have been published concentrating on serum samples from the first trimester [10, 11]. Both studies showed the same significant reduction of the PPI3 levels irrespective of whether the woman developed an early- or a late-onset type of preeclampsia. Furthermore, 2 recent reviews described PPI3 as one of the most promising markers to predict preeclampsia [19, 20].

The longitudinal first trimester testing of PPI3 helps strengthening the prediction of an elevated risk for a later development of preeclampsia and potentially identifying a cutoff for this syndrome. In addition, the repeated testing throughout the second and third trimesters appears to enable differential diagnosis of the anticipated pathology based on the slope of change between consecutive measurements, such as differentiating between early- and late-onset preeclampsia.

The biphasic changes in the release of PPI3 in preeclampsia compared to control cases raises the question as to how these alterations can be explained. The significantly lower values in the first trimester may find their explanation in an abnormal development of the placenta already at this stage of pregnancy. Although there are hypotheses that claim that these alterations should occur very early during placentation development, so far no proof for such changes have been presented. The changes in PPI3 release may be a first indicator of a dysregulated placental development early in pregnancy resulting in preeclampsia. It has to be noted though, that the reduced amounts of PPI3 are true for both groups of preeclampsia, early as well as late onset [10, 11, this study], while a general explanation for these very low levels early in gestation is missing.

The overshoot of PPI3 prior to and during the onset of clinical symptoms of preeclampsia is much easier to explain. It has been shown that trophoblast apoptosis is increased in preeclampsia [21]. Since apoptotic material is cleared in the lungs of pregnant women and will not result in activation of the maternal inflammatory system [22], and since elevated apoptosis has also been described for IUGR [23], increased apoptosis cannot account for the increase in PPI3 in preeclampsia. On the other hand, it has been postulated [24] that it is rather an increase in the rates of necrosis and apoptosis that may account for the increase in proteins and DNA in peripheral blood as well as account for the induction of the inflammatory response. This hypothesis is supported by a recent paper by Goswami et al. [25], who showed that subcellular fragments of the syncytiotrophoblast inside maternal blood are only elevated in preeclampsia but not in IUGR.

Longitudinal Determination of PPI3 during Development of Preeclampsia

Fetal Diagn Ther 2008;24:230–236

235
Conclusions

Testing of PP13 in maternal blood throughout pregnancy may enable us to view a proper placentonal development. Alterations of placentonal structure and function may be directly related to changes in the amount of PP13 released into maternal blood. Since such alterations can be visualized already during the course of the first trimester in pregnancy pathologies where a placentonal cause is expected, PP13 may be used as a tool to assess an abnormal development of the placenta in preeclampsia.

Acknowledgements

The authors would like to thank Dr. Gundula Hebisch from the Department of Obstetrics and Gynecology, University of Zurich, Switzerland, for providing us with the serum samples, and Uta Zahn from the Department of Anatomy II, University Hospital RWTH Aachen, Germany, for her excellent technical support in performing the immunohistochemical staining. The authors highly appreciated the permission to use the statistical modeling for the normal course of PP13 during pregnancy as developed by Howard Cuckle and Dr. Yossi Tal and the statistical assistance of Ido Kuhnreich.

This study was sponsored in part by a grant from Israel’s Chief Scientist (grant No. 31851) to Diagnostic Technologies covering the costs of shipping kits, testing PP13 and advisory statistical support. This study was supported by the European Union FP6 (Pregenesys, grant No. 037244).
