Abstract
It is still unclear whether lung edema can be monitored by microwave reflectometry and whether the measured changes in lung dry matter content (DMC) are accompanied by changes in PaO 2 and in pro- to anti-inflammatory cytokine expression (IFN-γ and IL-10). Right rat lung hili were cross-clamped at 37 °C for 0, 60, 90 or 120 min ischemia followed by 120 min reperfusion. After 90 min (DMC: 15.9 ± 1.4%; PaO 2: 76.7 ± 18 mm Hg) and 120 min ischemia (DMC: 12.8 ± 0.6%; PaO 2: 43 ± 7 mm Hg), a significant decrease in DMC and PaO 2 throughout reperfusion compared to 0 min ischemia (DMC: 19.5 ± 1.11%; PaO 2: 247 ± 33 mm Hg; p < 0.05) was observed. DMC and PaO 2 decreased after 60 min ischemia but recovered during reperfusion (DMC: 18.5 ± 2.4%; PaO 2: 173 ± 30 mm Hg). DMC values reflected changes on the physiological and molecular level. In conclusion, lung edema monitoring by microwave reflectometry might become a tool for the thoracic surgeon.

edema correlates with a functional loss or with an increase in inflammatory parameters. An in situ and in vivo ischemia-reperfusion model of the right rat lung was used to evaluate lung injury after a period of up to 2 h of ischemia at 37°C followed by 2 h of reperfusion. Lung injury was determined by measuring arterial oxygen pressure (PaO₂) levels, pro- and anti-inflammatory cytokine levels and edema formation. At the end of each experiment the results of dry matter content (DMC) obtained by microwave reflectometry were compared with the DMC determined by drying and weighing.

**Methods**

**Animal Model**

Male Wistar rats weighing 350–400 g were used in all experiments. Experiments have been approved by the ethics committee of the University of Heidelberg and animals received humane care in compliance with the European Convention on Animal Care (GV solas guidelines) throughout the experiments.

Anesthesia and analgesia were induced by 50 mg pentobarbital i.p. and 10 mg of ketamine i.m. The animal was placed on a heated plate. Catheters placed in the jugular vein and carotid artery monitored systemic pressures. Pressure-controlled ventilation was performed after tracheotomy and introduction of a 10-gauge cannula by a rodent ventilator (RUS-1301, Foehr Medical Instruments, Germany) at 60/min, FiO₂ 0.5. After these procedures, anesthesia and analgesia were maintained by continuous intravenous application of 45 mg/kg/h ketamine, 0.6 mg/kg/h midazolam and 0.24 mg/kg/h pancuronium.

A horizontal thoracotomy was performed to open the thorax anteriorly through the 6th intercostal space and parasternally until the first ribs. Two clamps were placed and muscles and intercostal vessels were ligated successively to avoid excessive bleeding (fig. 1).

All animals received 100 IU of heparin intravenously 15 min prior to ischemia to avoid thromboembolic events.

After careful preparation (fig. 1), the hilus of the right lung including upper, middle and lower lobes was laced by a silicone tube (OD 0.96 mm; Neolab, Heidelberg, Germany) in order be used later as a tourniquet.

For ischemia the tourniquet was pulled tight at expiration. The thorax was covered by a wet compress and a heating blanket coupled to a second heating blanket underneath the animal. Using a thermometer placed between the right middle and lower lobes the heating system guaranteed a temperature of 37 ± 0.25°C after 30 min of ischemia (fig. 2). During ischemia, the animals were ventilated at a frequency of 80 cycles/min at a flow of 0.8 l/min and a peak pressure of 150 mm H₂O.

For reperfusion, the lace was removed and alveolar recruitment was performed over a period of 5 s at a peak inspiratory pressure below 200 mm H₂O; thereafter the animals were ventilated at 60 cycles/min and a peak pressure of 150 mm H₂O.

**Experimental Protocol**

Animals were randomized to investigate the extent of reperfusion injury after 60 (I-60; n = 5), 90 (I-90; n = 6) and 120 min (I-120; n = 3) of ischemia at 37°C over a reperfusion period of 120 min versus sham-operated controls (sham; n = 6).

Systemic pressure and blood gases were monitored before ischemia (T1), at the start of ischemia (T2), at the end of ischemia (T3), at the start of reperfusion (T4) and at 30 min (T5), 60 min (T6) and
120 min of reperfusion (T7). The hemoglobin content of arterial blood was determined at the end of each experiment.

Cytokine mRNA Expression Analysis

Rats were sacrificed after 2 h of reperfusion. Thoracic organs were removed en bloc, and parts of the right lower lung lobe were shock frozen in liquid nitrogen. Total RNA was extracted using the RNeasy® kit (Qiagen, Hilden, Germany) with brief homogenization in a Mircera®-D-8 homogeniser (Art-moderner Labortechnik, Mülheim-Hügelheim, Germany) and with the usage of the QIAshredder® (Qiagen). cDNA synthesis was performed using oligo-dT primers and Superscript II® (Invitrogen, Kalsruhe, Germany) with 4 μg of RNA according to the manufacturer’s instructions.

PCR was performed as described elsewhere [10], using one eighth of the synthesized cDNA. The amounts of PCR products were determined by the Chemi Doc® and the Quantity One® (Bio-Rad, Munich, Germany). The results were arbitrarily normalized to the signals of β-actin cDNA. The primers used for amplification of β-actin, interleukin (IL) 10 and interferon (IFN) γ, are described elsewhere [10].

Edema Formation

Dry weight was determined by microwave reflectometry after opening of the thoracic cavity, during ischemia and during reperfusion. The results were compared to the DMC measured by drying and weighing lung tissue at 100°C for 48 h after each experiment to ensure safe electrical contact between the lung tissue surface and the probe. This check was performed in the right middle lobe and the left upper lobe.

Determination of Dry-to-Wet Ratio by Microwave Reflectometry

The dielectric properties of lung tissue were measured with an open-ended coaxial line probe, which was positioned in smooth contact with the lung surface. Measurements were performed both, at the beginning and end of ischemia, and at 0, 30, 60 and 120 min of reperfusion (T1–T7).

The probe diameter of the inner and outer conductor was 0.75 and 4 mm, respectively, which resulted in a penetration depth of 2.5 mm into the tissue corresponding to a sample volume of 33 mm³. The complex reflection coefficient of the interface between coaxial line and tissue was measured from 5 MHz to 3 GHz using a network analyzer HP 8753C in combination with an S parameter test set HP 86046 A (Hewlett Packard Co., Palo Alto, Calif., USA). The complex dielectric permittivity of the lung tissue was calculated from the reflection coefficient measured after system calibration as described elsewhere [11]. It took 25 s to acquire 1 spectrum.

We fitted 3 Debye spectral terms [12] (see equation 1) to the measured data, in order to extract the high-frequency dielectric permittivity ε_{w-tissue} related to tissue water content.

$$ε(ω) = ε(0) + \frac{σ}{2πf_i} + \frac{3}{2\pi f_i} \frac{Δε_i}{1 + \frac{2πf}{f_i}}$$

(1)

with ε₀ = 8.85 × 10⁻¹² As/Vm, ω = 2πf, f = frequency, i = imaginary unit (= −1), ε(●●) = 5. The parameters Δε_i, f_j = 1, 2, 3 and σ were subjected to a nonlinear least-square fitting algorithm. The relaxation time τ_j was found to be at about 10⁻¹¹ s, which is in the region of the relaxation time measured in pure water [13]. Therefore, we identified Δε_3 with the contribution of tissue water and the dielectric permittivity ε_{w-tissue} was calculated with:

$$ε_{w-tissue} = Δε_3 + ε(●●).$$

To determine the content of dry matter from the dielectric permittivity measurements we used a new dielectric model of lung tissue [9] describing the tissue as a mixture of water with the dielectric permittivity ε_w = 75 [13], dry matter with ε_{dry} = 3 [14] and air with ε_{air} = 1, each component having a corresponding volume fraction ν_i with i = w, dry, air. Applying this model, the volume fraction ν_w of water was calculated with the mixture formula of:

$$ν_w = \frac{ε_{w-tissue} - ε_w - ν_{dry} [ε_{dry} - ε_w]}{(1 - ν_w) [ε_{air} - ε_w] + ν_{air} [ε_{air} - ε_w]}$$

(2)

and the content of dry matter DMC_{dil} with equation 4 using ν_{dry} = 0.098 [9]:

$$DMC_{dil} = \frac{ρ_{dry}ν_{dry} + ρ_wν_w}{ρ_wν_w + ρ_{dry}ν_{dry}}$$

(3)

with ρ_{dry} = 1.4 g/cm³ [15] and ρ_w = 1.0 g/cm³. Analogously, equation 5 was used for the calculation of DMC_{weight} that was determined by drying and weighing:

$$DMC_{weight} = \frac{m_{dry}}{m_{wet}} - \frac{m_{dry}}{m_{dry} + m_{wet}} = \frac{ρ_{dry}ν_{dry} + ρ_wν_w}{ρ_wν_w + ρ_{dry}ν_{dry}}$$

(4)

with mass m_i, i = wet, dry of the wet and the dry tissue.

Histological Sections

Samples were taken from the mediastial superior part of the right lower lung lobe, put in specimen molds, filled and covered with Tissue-Tek (Sakura, Zoeterwoude, Netherlands) and were put into liquid nitrogen to be stored at −80°C thereafter. Native tissues were sectioned at 5 μm by a cryostat microtome (CM 3000, Leica/Jung, Germany). The slides were air-dried at room temperature for 12–24 h and then were either processed directly or stored at −30°C. Histological evaluation was performed blinded for all specimens by standardized HE and PAS staining.

Statistical Analysis

For group comparison, the results were quoted as means ± STD (standard deviation). Statistical differences between data sets during ischemia and reperfusion (T1–T7) were calculated using ANOVA multivariate analysis followed by the double-sided post hoc test of Dunnet. Statistical differences of expression analysis were calculated by the nonparametric rank sum test of Mann, Whitney and White. The null hypothesis was rejected when p ≤ 0.05.

To compare DMC_{dil} from dielectric measurements with the results from drying and weighing, the lung tissue DMC_{weight}, we used the statistical method of Bland and Altman [16].

Results

Lung temperature during ischemia was adjusted to 37.0°C which was reached about 30 min after the cooling period during the surgical preparation (fig. 2). At the end of each experiment, the hemoglobin content in arterial blood was similar in all investigated groups (control: 11.8
Monitoring of Lung Edema by Microwave Reflectometry

1.1 g/dl; I-60: 11.9 ± 0.9 g/dl; I-90: 11.0 ± 0.9 g/dl; I-120: 11.4 ± 1.0 g/dl).

Arterial oxygenation dropped throughout reperfusion in the contingent with 90 min of ischemia and was significantly reduced compared to sham-operated animals (I-90: 76.7 ± 17.5 mm Hg; sham: 247.0 ± 33.9 mm Hg; p < 0.01; table 1). After 120 min of ischemia, the animals developed lethal PaO₂ values compared to sham-operated controls and died within 30 min of reperfusion (I-120: 43.7 ± 7.1 mm Hg; sham: 206.4 ± 34.7 mm Hg; p < 0.01). PaO₂ values of I-60 animals dropped during the first 30 min of reperfusion compared to controls, but recovered thereafter compared to sham-operated controls (fig. 3).

The comparison of DMC<sub>diel</sub> at the end of each experiment with DMC<sub>weight</sub> found by drying and weighing in the Bland-Altman plot in figure 4 shows that 95% of all differences were within the limit of ± 2.3%.

A significant decrease in DMC<sub>diel</sub> was observed during the first 30 min of reperfusion (T5) in I-90 and I-120 (sham: 19.1 ± 1.50%; I-90: 16.2 ± 2.30%; I-120: 12.8 ± 0.60%; p < 0.05) and at T7 of I-90 compared to sham-operated controls (I-90: 15.4 ± 1.43%; sham: 19.5 ± 1.11%; p < 0.05, fig. 5). DMC<sub>diel</sub> in group I-60 also showed a minimum at T3 (n.s.), but in contrast to I-90 and I-120 a recovery to control values was observed at T7.

At the end of each experiment a significant increase in IFN-γ on β-actin expression was observed in lung

**Fig. 3.** Changes in PaO₂ values. A significant loss of PaO₂ values occurred during the first 30 min of reperfusion in all investigated groups compared to sham-operated controls (* p < 0.01), which persisted in I-90 over 2 h of reperfusion (* p < 0.01). I-60 animals recovered from this loss of oxygenation whereas I-120 animals died.

Stable arterial pressures were monitored in all groups. In I-90 animals, arterial pressures were lower during reperfusion compared to sham-operated controls (* p < 0.05).
The increase in IFN-$\gamma$/H9253 expression resulted in an increased pro- to anti-inflammatory cytokine expression of IFN-$\gamma$/IL-10 in this group (I-90: 3.311 ± 0.535; sham: 1.636 ± 0.132; p < 0.01; fig. 6). I-60 and I-90 animals did not show a significant increase in neither IFN-$\gamma$ nor IL-10 (fig. 6).
The HE staining of the injured lungs showed the typical formation of pulmonary edema in different stages. The alveoli were filled with a homogenous, generally acellular, eosinophilic fluid (fig. 7a, b). However, the morphological extent of reperfusion injury after 60, 90 and 120 min of ischemia differed greatly and did not correlate with the functional data. All sham-operated controls were identified and showed collapsed alveoli due to the large amount of elastic fibers in the rat lung (fig. 7c, d).

**Discussion**

Various studies describe the assessment of lung edema by transthoracic bioimpedance measurements in pulmonary critical care, but the method has been found to be critical in lung tissue [17, 18]. Measurements depend on the variations of air volume within the tissue, on a number of factors including body weight and position, lung volume and pleural effusions. Compared to the transthoracic bioimpedance method, our microwave reflectometry system requires the contact between probe and tissue, and an application to patients is only possible during surgical operations with an open thorax. But microwave reflectometry gathers information directly from the tissue and the reflection coefficient depends on the dielectric properties of the lung. The main contribution to the dielectric properties of lung tissue beyond 1 GHz is the polarization of water molecules because other contributions to the dielectric spectrum disappear due to their relaxation frequency in the MHz region [14]. The dielectric permittivity $\varepsilon_{w\text{tissue}}$ of lung tissue in the GHz region can be changed by changing the volume fraction of the nonpolar matter or the volume fraction of water as described by the mixture formula in equation 3. Changes in ion composition during ischemia are in the order of magnitude of millimoles per liter which has only small effects on the volume fraction. The conductivity of the electrolytes is mainly affected by this ion composition change but their effect on the real part of the complex dielectric permittivity is small (see equation 1). Therefore, data analysis with our model enables the online monitoring of lung edema by monitoring the dielectric properties of water molecules and quantification of the DMC is possible. However, there are some experimental sources of error which might reduce measurement accuracy and impede a better correlation between $DMC_{\text{dist}}$ and $DMC_{\text{weight}}$. For instance, dielectric lung properties showed a jitter due to the spirometric state of inspiration and expiration. Jitter frequency from artificial ventilation was 80/min. One sweep of the network analyzer HP 8753C took 25 s so
that the jitter affected each spectrum. We overcame this problem by using a curve fitting method [19] to calculate the averaged dielectric permittivity $\varepsilon_{w\text{-tissue}}$. Another error source was the contact between the coaxial line probe and the surface of the ventilated lung. In our setup, the probe was fixed by an inelastic carrier and safe contact to the lung tissue surface required a moderate force. However, the pressure tolerance of lung tissue is very small and in some experiments the contact area was slightly deformed. On the other hand, the contact was not sufficient in the case of too small a pressure. The main error source of the method of drying and weighing was due to the varying amount of liquid on the surface of the small lung samples which distorted the dry-to-wet ratio. In spite of these deficiencies, the Bland-Altman plot in figure 3 shows that 95% of all measured differences between $DMC_{weight}$ and $DMC_{diel}$ were found in an interval of $\pm 2.3\%$. Therefore, the method of measurement of $DMC_{dier}$ by microwave reflectometry is sensitive enough to detect differences in absolute DMC between the control group (sham: $19.1 \pm 1.50\%$) and lung tissue strongly damaged by ischemia (I-120: $12.8 \pm 0.60\%;$ fig. 5).

The parameter $DMC_{dier}$ seems to be sensitive enough to detect a significant increase in lung edema in I-90 compared to controls during reperfusion (fig. 5; $p < 0.05$) and therefore it could be a helpful diagnostic tool to assess lung injury during posts ischemic reperfusion.

Warm ischemic tolerance of the nonventilated lung is described to be up to several hours [5–7]. Within this period we found that 90 min of lung ischemia at 37°C results in significant and reproducible reperfusion injury in all investigated parameters (fig. 3–6). Animals of the I-60 group did show lung injury at the start of reperfusion but recovered more and more during the reperfusion period.
of 2 h (fig. 2–4). Van Raemdonck et al. [5] compared the influence of an increasing postmortem interval on graft function in an isolated, room-air-ventilated rabbit lung model during blood reperfusion and found no significant differences after 1-hour ischemia compared to nonischemic lungs. There are several possible reasons for the different findings, e.g. in vivo versus the ex vivo animal model, and different organ temperatures (37°C vs. room temperature). All 3 animals of I-120 died within the first 30 min of reperfusion. A significant increase in lung weight gain with marked edema in the histological cross-sections and a significant decrease in arterial oxygenation has been shown during this period. However, no changes have been observed in IFN-γ and IL-10 mRNA expression levels in lung tissue. Both, the higher extent of ischemia-reperfusion injury and the short duration of the reperfusion period seemed to limit the alteration of mRNA expression. Palazzo et al. [20] demonstrated in a model of left lung ischemia-reperfusion in dogs that a period of 120 min of warm ischemia results in significant lung injury also of the contralateral lung, but this was not at all close to being lethal. These findings are similar to others, which limit the maximum safe warm ischemic period of deflated lungs to 2 h [6, 21–23]. However, all authors investigated lung ischemia at room temperature (20–22°C) resulting in significantly lower organ temperatures. This differs significantly from our model, in which organ temperature is kept at 37 ± 0.2°C. This temperature was always reached within the first 25–35 min of ischemia (fig. 2). Circulating air at the opened thorax might influence ischemic tolerance of the lung. This problem has been overcome by Date et al. [24] using a different approach. A cooling jacket for lung grafts during the reimplantation period was used, and rewarming of the graft was prevented compared to no cooling or intermittent saline cooling [24].

Factors beside temperature which might additionally influence ischemic tolerance include operative preparation of hilar structures and well-being of the animal. Compared to the model of Eppinger et al. [2], no dissection of hilar structures of the right lung (vessels and bronchus) was carried out in our model. This makes our model easier to use, limits the dropout rate and limits major operative damage to these structures.

According to the theory of West and Dollery [25], positioning influences the distribution of ventilation and perfusion of both lungs significantly. Therefore, we presumed that the animal in a supine position has a more homogenous perfusion and ventilation on each lung side in comparison to side positioning, especially after injury of one side [2, 6, 20].

Conclusions

Warm ischemic time tolerance of the lung at 37°C was found to be between 60 and 90 min. Within the first 2 h of reperfusion, a significant increase in proinflammatory mediators on the molecular level has been observed, accompanied by loss of oxygenation and gain of lung edema. In this case, the measurement of pulmonary edema by microwave reflectometry could be a helpful diagnostic tool to assess lung injury during surgical operations with an open thorax.
