Abstract

Background: White matter hyperintensities (WMH) on MRI scans indicate lesions of the subcortical fiber system. The regional distribution of WMH may be related to their pathophysiology and clinical effect in vascular dementia (VaD), Alzheimer's disease (AD) and healthy aging. **Methods:** Regional WMH volumes were measured in MRI scans of 20 VaD patients, 25 AD patients and 22 healthy elderly subjects using FLAIR sequences and surface reconstructions from a three-dimensional MRI sequence. **Results:** The intraclass correlation coefficient for interrater reliability of WMH volume measurements ranged between 0.99 in the frontal and 0.72 in the occipital lobe. For each cerebral lobe, the WMH index, i.e. WMH volume divided by lobar volume, was highest in VaD and lowest in healthy controls. Within each group, the WMH index was higher in frontal and parietal lobes than in occipital and temporal lobes. Total WMH index and WMH indices in the frontal lobe correlated sig-

nificantly with the MMSE score in VaD. Category fluency correlated with the frontal lobe WMH index in AD, while drawing performance correlated with parietal and temporal lobe WMH indices in VaD. **Conclusions:** A similar regional distribution of WMH between the three groups suggests a common (vascular) pathogenic factor leading to WMH in patients and controls. Our findings underscore the potential of regional WMH volumetry to determine correlations between subcortical pathology and cognitive impairment.

Introduction

Clinicopathological studies indicate that diffuse hyperintensities in the deep subcortical white matter (so-called white matter hyperintensities, WMH) on T₂-weighted magnetic resonance imaging (MRI) scans represent ischemic damage of the subcortical fiber system [1–3]. Diffuse WMH are most prevalent in vascular dementia (VaD) [4] but are also reported in 27–92% of the elderly population [5, 6]. An increase in WMH in patients with Alzheimer's disease (AD) compared to age-matched healthy elderly

³ Not different between groups, $\chi^2 = 1.9$ with 2 d.f., $p < 0.39$.

⁴ Significantly different between groups, $\chi^2 = 8.3$ with 2 d.f., $p < 0.02$.

subjects is still controversial [4, 7, 8]. In the elderly population, WMH increase with age, cerebrovascular disease and hypertension [5, 9, 10].

Several studies reported a significant correlation between WMH and reduced performance in specific cognitive domains in nondemented elderly subjects, particularly in subjects with a history of hypertension [5, 10–12], but these findings are controversial [13–15]. WMH have been suggested to accelerate cognitive decline in individuals with mild cognitive impairment [16, 17] and were related to reduced performance in several neuropsychological tasks in AD and VaD. Other studies failed to show any relationship between WMH and cognition in AD [18] or found no relationship between WMH and cognitive performance independently of associated hippocampal and cortical atrophy in a group of VaD and AD patients [19, 20].

The regional distribution of WMH in different disorders is of potential interest, because not only the extent, but also the localization of a lesion determines its clinical significance independently of the extent of the lesion. For example, relatively small lesions in the thalamic nuclei have strong effects on cognitive functioning [21], while WMH widely distributed in the subcortical white matter may remain clinically silent [22]. Furthermore, different localizations of WMH may reflect pathogenic differences. Neuropathological studies suggest a differential susceptibility of cerebral regions for vascular pathology [23]. In

VaD, the frontal lobe appeared to be more vulnerable to white matter pathology than other lobes [24–26].

So far, only few studies considered the regional distribution of WMH in dementia [4] or aging [6]. These earlier studies used semiquantitative rating scales, and these studies did not always account for differences in lobar volumes.

In this study, we used a semiautomated segmentation technique to determine lobar WMH indices to be compared between groups of VaD and AD patients and healthy subjects. We also investigated whether lobar WMH indices correlated with domain-specific cognitive impairment and age.

Materials and Methods

Subjects

We studied 25 patients with the clinical diagnosis of probable AD according to NINCDS-ADRDA criteria [27], 20 patients with the clinical diagnosis of probable VaD according to NINDS-AIREN criteria [28] and 22 healthy controls. Subjects were recruited from the Department of Psychiatry, University of Munich, Germany, and the Alzheimer Center, Vrije Universiteit Medical Center, Amsterdam, the Netherlands. Subject characteristics are presented in table 1.

Severity of dementia was determined according to the Mini Mental State Examination (MMSE) score [29]. One AD patient was severely demented (MMSE < 10), 12 AD and 5 VaD patients were moderately demented ($9 < \text{MMSE} < 21$), and 17 AD and 15 VaD patients were mildly demented (MMSE > 20). Dutch controls were

recruited among spouses and friends of patients with dementia. The Dutch controls completed the CAMCOG, the MMSE, the MADRS and the CUSPAD. German controls were healthy volunteers recruited from elderly members of a local parish. The German controls completed the cognitive battery of the Consortium to Establish a Registry for Alzheimer's Disease (CERAD), the HAMD and the SIDAM. Exclusion criteria were history or presence of depression, dementia or mild cognitive impairment and history or presence of any other significant neurological, physical or psychiatric disorder including drug and alcohol misuse.

Two Dutch controls had a history of hypertension but showed normal values after treatment; German controls had no history of hypertension and had normal blood pressure at the time of clinical examination. Four German and 5 Dutch VaD patients had a history of hypertension. Two German and 2 Dutch AD patients had a history of hypertension but showed normal values after treatment.

The reliability of WMH measurement was evaluated in an independent group of 10 German subjects. This group comprised 2 healthy elderly subjects, 6 patients with clinical probable AD and 2 patients with mixed dementia (mean age \pm SD was 74.9 ± 8.4 ; female-to-male ratio was 7/3).

Informed written consent was asked and received from all patients and healthy subjects. Both ethical committees of the Ludwig Maximilian University, Munich, Germany, and the Vrije Universiteit Amsterdam, The Netherlands, approved of the study.

Magnetic Resonance Imaging

MRI examinations were performed on a 1.5-tesla Siemens Magnetom Vision MRI scanner for the German subjects and on a 1.0-tesla Siemens Magnetom Impact MRI scanner for the Dutch subjects (both scanners from Siemens, Erlangen, Germany). All subjects had a volumetric T₁-weighted sagittally oriented MRI sequence (for German subjects: TR = 11.6 ms, TE = 4.9 ms, resolution = 0.94 by 0.94 by 1.2 mm; for Dutch subjects: TR = 15 ms, TE = 7 ms, resolution = 0.98 by 0.98 by 1.0 mm). Some scans were done with an inplane resolution of 0.5 mm by 0.5 mm; these scans were blurred to a resolution of 0.94 by 0.94 mm with trilinear interpolation using Analyze AVW software (Mayo Foundation, Rochester, Minn., USA). Additionally, an axially oriented fast FLAIR sequence (for German subjects: TR = 9,000 ms, TE = 110 ms, resolution = 0.94 by 0.94 by 6 mm; for Dutch subjects: TR = 9,000 ms, TE = 105 ms, resolution = 0.98 by 0.98 by 5 mm) was obtained.

Regional Distribution of WMH

An anatomical template was made to identify the borders of frontal, parietal, temporal and occipital lobes, using the volumetric T₁-weighted sequence and Analyze AVW software (Mayo Foundation) as previously described [30]. After editing the brain volume from all nonbrain tissue, the anatomical borders of the 4 lobes were determined on the surface reconstruction of the brain, using anatomical landmarks and simple geometrical constructions [30]. The frontal-parietal border was defined by the sulcus centralis, and the frontal-temporal border was determined by the sulcus lateralis. The parieto-occipital, the temporo-occipital and the parietotemporal borders were defined by a geometrical construction (fig. 1). The anatomical template was reconstructed in the orientation and resolution of the corresponding FLAIR weighted axial slices, using an affine transformation (AIR 3.08) [31]. WMH volumes were measured on the FLAIR sequence. The lesions were semiautomatically traced, using a region growing algorithm based on pixel intensity (fig. 1).

Lesions were manually edited, if visual inspection suggested inconsistencies of the automated segmentation. The number of voxels within each lesion was summed automatically and multiplied by the voxel size to obtain absolute values (mm³) for the lesions. The outer borders of the lobes were easily identified on the axial FLAIR sequence by comparing with the corresponding anatomical template. Internal lobar boundaries were determined according to well-described criteria (Psychiatry Research, Neuroimaging Section, accepted). The sum of lesions within each lobe gave the absolute WMH load for each lobe. Lesions that crossed a lobar border were divided along this border, and each part was attributed to the corresponding lobe. Lobar WMH indices were calculated by dividing lobar WMH volume by lobar volume. The total WMH index was calculated by dividing the sum of WMH volumes across lobes by total brain volume. Total brain volume and lobar volumes were measured on the T₁-weighted volumetric scans according to a well-described method (Psychiatry Research, Neuroimaging Section, accepted). All WMH indices are expressed as percent $\times 10^{-2}$ of lobar volume to simplify reporting of numbers.

Neuropsychological Examination

Cognitive performance was investigated in a subgroup of 17 AD and 6 VaD patients from the German center and a subgroup of 5 VaD patients from the Dutch center. German patients were tested with the cognitive battery of the CERAD [32], Dutch patients were tested using the cognitive battery of the Alzheimer's Disease Assessment Scale (ADAS) [33]. In addition to the ADAS, delayed 10-word list recall and animal category verbal fluency were tested in Dutch patients. To account for difference in the scoring of the CERAD and the ADAS, scoring criteria of the CERAD were used for both German and Dutch patients. To account for the different number of items in the recognition and the naming task between German and Dutch patients, percentage scores were calculated for these tasks by dividing the number of correct responses by the maximum score.

Statistics

WMH indices were not normally distributed within groups, as shown by the Shapiro-Wilks test and visual inspection of histograms. To control for potential effects of age and center, between-group differences in WMH load were assessed using univariate analysis of covariance with ranked regional WMH indices as dependent variables and age, center and diagnosis as predictors. The regional distribution of lobar WMH indices within each group was tested using the Wilcoxon signed-ranks test. Correlations between WMH indices and neuropsychological measures and age were controlled for confounding effects of center, using partial correlation on the rank-transformed WMH indices.

To determine the reliability of WMH measurements by different raters, the intraclass correlation coefficient (ICC) was determined by measuring WMH of 10 subjects by 2 independent investigators twice (L.G. and Y.Z.), blinded to clinical diagnosis.

Results

As shown in table 2, after accounting for the effects of age and center, total and regional WMH indices were significantly higher in VaD patients than in healthy controls. Furthermore, total and regional WMH indices were sig-

Fig. 1. Surface map for tracing of lobar borders and axial FLAIR images with regional segmentation. The letters A, B, C, D, E, H and X denote the intersections of lines or reference points. A is the endpoint of the ascending branch of the sulcus lateralis. B is at the parieto-occipital sulcus. Through C, the center of the line AB, a line CH was drawn perpendicularly to the line AB. D was determined along the line CH, where it intersects the tissue/nontissue border of the brain. The midpoint along line CD is denoted X, from which a line was drawn to A and to B. FLAIR images with semiautomatically traced WMH are overlaid with the corresponding anatomical template indicating different regions of the brain (shown with different line patterns, arrowheads are indicating borders between lobes).

Table 2. Regional WMH indices in percent $\times 10^{-2}$ of respective lobe volume

	Comparison subjects		AD patients		VaD patients		Ancova (d.f. = 2, 62)	
	mean	SD	mean	SD	mean	SD	F	p
Total	1.55	2.12	3.77	3.96	24.53	28.19	13.4	<0.001 ^{a, b}
Frontal	3.05	4.10	6.80	9.92	45.84	55.43	7.1	<0.002 ^{a, b}
Parietal	2.87	5.15	7.02	5.68	48.57	56.16	18.8	<0.001 ^{a, b, c}
Temporal	0.71	1.01	1.65	3.98	4.97	6.16	6.7	<0.002 ^{a, b}
Occipital	0.58	1.14	3.34	5.99	8.99	13.16	4.4	<0.02 ^{a, c}

Ancova = Analysis of covariance on rank-transformed values of WMH indices: overall group effect, covariates were age and center.

^a The WMH index was significantly higher in VaD than in controls (Ancova; d.f. = 1, 38; with age and center as covariates, $p < 0.02$).

^b The WMH index was significantly higher in VaD than in AD (Ancova; d.f. = 1, 41; with age and center as covariates, $p < 0.001$).

^c The WMH index was significantly higher in AD than in controls (Ancova; d.f. = 1, 43; with age and center as covariates, $p < 0.03$).

Fig. 2. Regional distribution of WMH indices. Lobar WMH index = WMH volume/lobar volume $\times 10^4$; * = higher compared to temporal ($p < 0.001$) and occipital WMH indices ($p < 0.05$); † = higher compared to occipital WMH index ($p < 0.001$); ‡ = higher compared to temporal WMH index ($p < 0.05$).

nificantly higher in VaD than in AD patients, with the exception of the occipital WMH index. In the AD group, parietal and occipital WMH indices were significantly higher compared to controls. Using absolute WMH volumes instead of WMH indices did not alter the significance of these effects.

A regional analysis of WMH variations within each group showed that WMH indices were generally higher in the frontal and parietal lobes than in the temporal and occipital lobes (fig. 2). A similar analysis with absolute WMH volumes showed more WMH in the frontal lobe than in the parietal lobe, and higher WMH volumes in the parietal lobe than in the temporal and occipital lobes ($p < 0.05$ for all comparisons).

In the VaD group, the total WMH index and WMH index of the frontal lobe were correlated with the MMSE score, including control for a potential difference between the centers ($r = -0.53$, $p < 0.01$, and $r = -0.47$, $p < 0.001$, respectively; fig. 3a and b). Parietal and temporal WMH indices were significantly correlated with drawing ($r = 0.66$, $p < 0.05$, and $r = 0.63$, $p < 0.05$, respectively; fig. 3c). In the AD group, there were no significant correlations between MMSE scores and total or regional WMH indices (r between -0.13 and 0.25 , $p > 0.24$). Verbal category fluency was correlated with the frontal lobe WMH index ($r = 0.51$, $p < 0.05$; fig. 3d). The significance of these correlations remained unchanged when using absolute WMH volumes. There were no significant correlations

between regional WMH indices and naming, verbal learning, recall or recognition in the AD and VaD groups.

Total WMH index and regional WMH indices in the frontal, parietal and occipital lobes were positively correlated with age in the AD group when controlling for center ($r = 0.63$, $p < 0.001$; $r = 0.48$, $p < 0.05$; $r = 0.52$, $p < 0.01$; $r = 0.44$, $p < 0.05$, respectively). Total and parietal WMH were significantly correlated with age in the control group when controlling for center ($r = 0.45$, $p < 0.05$, and $r = 0.64$, $p < 0.01$, respectively). WMH indices did not correlate with age in the VaD group. Correlations with age remained unchanged for absolute WMH volumes.

The ICC for measurements of the total WMH index was 0.996. The ICC for measurements of regional WMH indices was 0.99 in the frontal lobe, 0.81 in the parietal lobe, 0.998 in the temporal lobe and 0.72 in the occipital lobe.

Discussion

In the present study, we used a new MRI-based method to measure regional WMH load. We found that WMH indices, i.e. WMH volume normalized to lobar volume, were more pronounced in VaD patients than in AD patients and healthy controls. The distribution of WMH across cerebral lobes was similar between groups, with frontal and parietal lobes showing the highest and occipital and temporal lobes showing the lowest WMH load. The WMH indices correlated with age in healthy controls and AD patients, but not in VaD patients. Dementia severity correlated with WMH indices in VaD, but not in AD patients. There were correlations between domain-specific cognitive impairments and regional WMH indices in AD and VaD patients. To assure that the effects in WMH indices were due to WMH changes and not to changes in lobar volume, all analyses were repeated with absolute WMH volumes.

One improvement of this study compared to earlier studies is the use of a standardized protocol to quantitatively assess regional WMH load. Although several scales exist for visual rating of WMH on MRI [34, 35], only few of them include regional lobar distribution of WMH [14, 15, 36, 37]. Few methods were developed that provide quantitative measures to examine WMH load on MRI, and none of these examined regional WMH volumes [10, 18, 19, 38]. Interrater reliability for the measurement of total WMH load with an ICC of 0.99 in our study compares to previous quantitative methods with ICC ranging from 0.97 [18] to 0.99 [19]. The ICC for regional WMH in

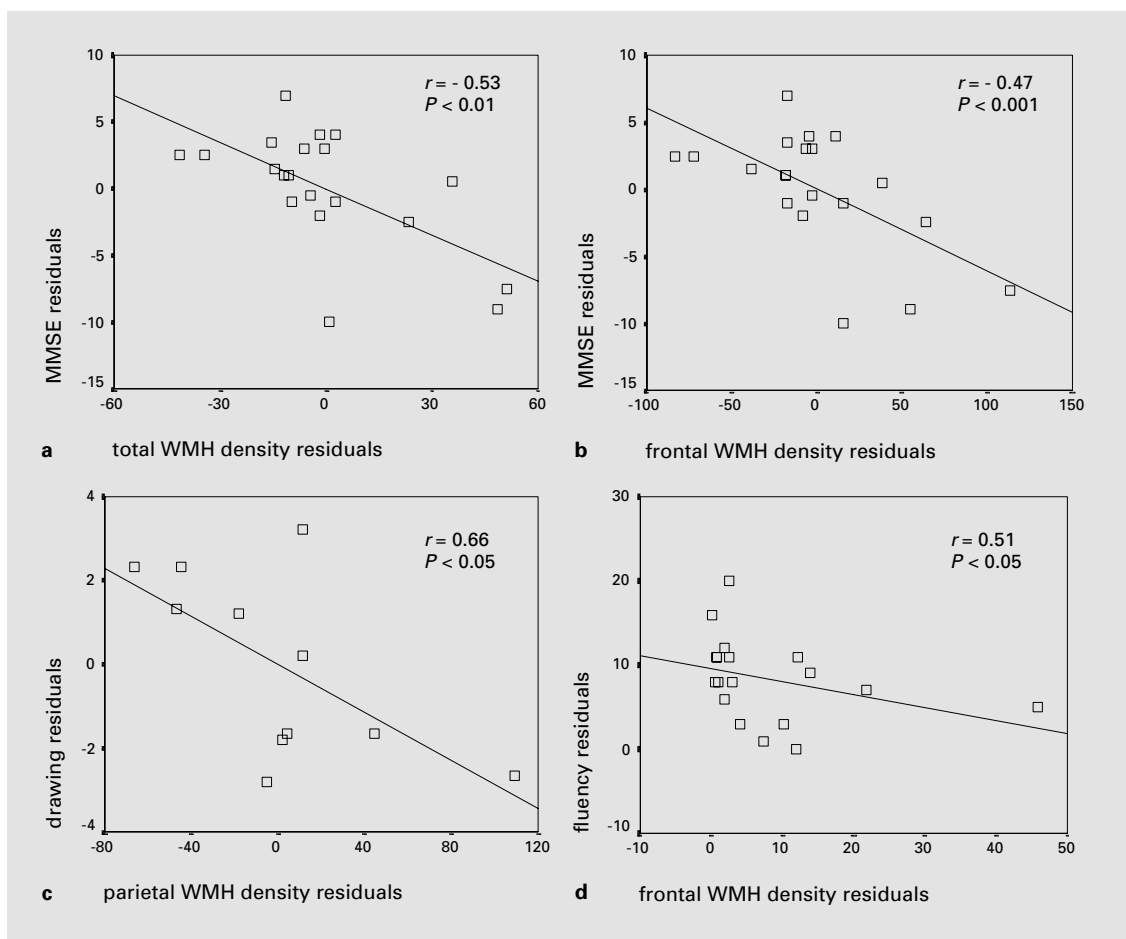

Fig. 3. Cognitive measures and WMH indices in VaD and AD. Scatter plot of residuals of MMSE score and total **(a)** and frontal **(b)** WMH indices controlled for center in the VaD group, of drawing score and parietal WMH index controlled for center in the VaD group **(c)** and of fluency score and frontal WMH index controlled for center in the AD group **(d)**.

our study ranged from 0.99 for the frontal lobe to 0.72 for the occipital lobe. To our knowledge there are no previous reports on the interrater reliability of regional WMH measurements. Our method is based on a recently reported segmentation technique to generate an anatomical template for subsequent lesion allocation [30]. The frontal lobe is segmented with reference to anatomical landmarks only, whereas the other lobes are segmented by a combination of anatomical landmarks and a geometrical construction. This may, at least in part, account for the differences in measurement accuracy of WMH across lobes.

Higher WMH indices in VaD patients compared to AD patients and healthy controls, even after controlling for age and center effects, are consistent with previous studies [4, 39]. Parietal and occipital, but not total WMH

indices were significantly increased in AD patients compared to healthy controls. This suggests that in AD certain regions are more strongly involved in white matter pathology than others. Such a region-specific WMH increase may be overlooked when only total WMH load is examined. This may explain controversial findings on total WMH load in AD from earlier studies [4, 7, 8, 40].

Regional distribution of WMH indices across lobes was similar between groups. WMH indices were higher in the frontal and parietal lobes than in the occipital and temporal lobes in the demented patients and the healthy controls. Earlier studies described a strong involvement of the frontal and/or parietal lobes in demented patients and healthy elderly subjects using semiquantitative rating scales [4, 6, 15, 40, 41]. It has been suggested that over-

representation of the frontal and parietal lobes on axial slices might explain these findings [40]. Consistent with this notion, the absolute frontal WMH volume was highest compared to all other lobes in all groups. But even after normalization to lobar volumes, WMH load was higher in frontal and parietal than in temporal and occipital lobes. Findings from other imaging modalities also suggest that subcortical lesions may be most predominant in the frontal lobe. In computer-assisted tomography scans, leukoaraiosis was predominantly localized in the frontal region in mildly to moderately demented VaD patients, and only with severe dementia was leukoaraiosis more diffusely distributed throughout the brain [42]. Frontal leukoaraiosis correlated with reduced frontal lobe cerebral blood flow in mildly to moderately demented VaD patients [42]. In diffusion-weighted MRI of VaD patients the anterior region, particularly the frontal lobe, exhibited more abnormalities in water diffusion than the posterior regions of the brain [43]. Several neuropathological studies found chronic ischemic lesions predominantly in the frontal lobes and/or parietal lobes [24–26, 44, 45] suggesting an increased susceptibility of these lobes for white matter pathology.

In our VaD patients, dementia severity as measured by MMSE correlated with total and frontal lobe WMH indices. Furthermore, in a subgroup of the VaD patients measures of drawing performance were correlated with parietal and temporal lobe WMH indices. This location agrees with a large range of neuropsychological studies on patients with impaired drawing performance due to focal cerebral lesions in the bilateral or right parietal lobe [46]. There were no correlations between measures of episodic or semantic memory and regional WMH load. Similarly, Cohen et al. [47] reported correlations of global WMH load with visual-construction and executive-function measures, but not with measures of memory and verbal function in 24 VaD patients. This study, however, did not assess regional WMH load. There were no correlations between MMSE score and total and regional WMH in our AD patients, consistent with other studies [13, 48]. This suggests that either WMH in AD have not the same cognitive significance as in VaD or that AD pathology obscures the effect of WMH on cognition in AD. In AD patients without cerebrovascular disease, the main reason for cognitive impairment is AD-specific cortical pathology and WMH may only contribute to a lesser degree to the cognitive dysfunction.

In a subgroup of AD patients verbal category fluency correlated with the frontal lobe WMH index. Verbal fluency is a semantic function, involving speed of mental

processing and attention, and relays on prefrontal lobe functional integrity [49]. It has been found that WMH load, especially in the anterior region, is strongly correlated with verbal fluency scores in patients with cerebrovascular disease and stroke [50] and that WMH in healthy elderly subjects shows a strong correlation with performance of frontal lobe functions [10, 12]. However, these findings should be regarded as preliminary, because the number of patients in each group was small.

The similar regional distribution of WMH in VaD, AD and healthy aging suggests that these conditions might share a common pathologic factor for the occurrence of WMH. WMH in the AD and the control group may reflect vascular comorbidity. Indeed, white matter pathology in AD has been linked to ischemic changes [44] that are superimposed on the AD-specific pathology. An age-related increase in vascular comorbidity may underlie the significant correlation between age and total WMH load in AD patients and controls found in our and previous studies [48, 51]. In contrast, disease-specific vascular pathology would by far exceed an age-related increase in vascular comorbidity in VaD patients, thereby masking correlations between age and WMH load.

In the present study, we investigated healthy elderly controls as well as demented patients with relatively low cardiovascular comorbidity, such as hypertension or diabetes. Therefore, our results represent the effects of healthy aging, pure AD and pure VaD on regional subcortical lesions. For the same reason, however, one has to be careful in conferring our findings on the general elderly population, which has a much higher prevalence of cardiovascular comorbidity.

Our findings do underscore the potential of regional WMH volumetry to determine functional consequences of subcortical pathology in different disease conditions. We propose to use regional WMH volumetry in future studies on the general elderly population.
