Abstract

A new method for testing linear restrictions in linear regression models is suggested. It allows to validate the linear restriction, up to a specified approximation error and with a specified error probability. The test relies on asymptotic normality of the test statistic, and therefore normality of the errors in the regression model is not required. In a simulation study the performance of the suggested method for model selection purposes, as compared to standard model selection criteria and the t-test, is examined. As an illustration we analyze the US college spending data from 1994.

Keywords asymptotic normality, linear regression, model selection, model validation

1 Introduction

The choice of the relevant covariates in a linear regression model is an important and much studied problem. For this purpose, various methods have been suggested in the literature. One approach is via model selection criteria. Here one chooses the sub-model which minimizes a certain criterion function, e.g. the AIC (Akaike, 1974) or the BIC (Schwarz, 1978). Another approach is to specify the sub-model by testing the relevant linear restrictions. Toro-Vizcarrondo and Wallace (1968), see also Wallace (1972), observed that the sub-model may be superior to the complete model in terms of mean square error (MSE) even if the sub-model is incorrect. Therefore they suggested to test in which model the least squares estimator has smaller MSE. In this paper we suggest a related test which focuses on validating the sub-model. More precisely, the test allows to validate the sub-model up to a certain specified approximation error, and with a specified error probability. The test is based on asymptotic normality of the test statistic and therefore does not require normality of the errors in the regression model.

This paper is organized as follows. In Section 2 we introduce the model and the testing problem. Section 3 presents the test statistics and its asymptotic distribution. Further we discuss how to perform the test. In Section 4 we investigate the performance of our method, as compared to the t-test and some model selection criteria in a simulation study. Finally, in Section 5, we illustrate the practical usefulness of our method by analyzing the US college spending data from 1994.

2 Testing problem

Consider the homoscedastic linear regression model

\[ Y = X\beta + \epsilon, \] (1)

where \( Y \in \mathbb{R}^n \) is the response vector, \( X \in \mathbb{R}^{n \times (p+q)} \) is the design matrix, which is assumed to be non-random, and \( \beta \in \mathbb{R}^{p+q} \) denotes the unknown regression parameter vector of interest. The errors \( \epsilon = (\epsilon_1, \ldots, \epsilon_n) \) are assumed to be independent identically distributed (i.i.d.) random variables with \( E(\epsilon_1) = 0 \) and \( \text{Var}(\epsilon_1) = \sigma^2 \).

Suppose that we want to check the validity of the sub-model

\[ Y = X_1\beta_1 + \epsilon, \] (2)

where \( X = [X_1, X_2] \) and \( X_1 \in \mathbb{R}^{n \times p}, \ X_2 \in \mathbb{R}^{n \times q}, \) and \( \beta' = [\beta_1', \beta_2'] \), where \( \beta_1 \in \mathbb{R}^p, \ \beta_2 \in \mathbb{R}^q. \) Classically one verifies model (2) by testing the hypothesis

\[ H_0 : \beta_2 = 0. \]

Let \( \hat{\beta} \) denote the least squares (LS) estimator in the full model (1), and let \( \hat{\beta}_r \) be the restricted LS estimator in the submodel (2), which we also consider as a \((p+q)\)-dimensional vector by filling the last \( q \) entries by 0. Suppose for the moment that in addition the errors
are normally distributed, and let $SSE(b)$ denote the error sum of squares of an estimator $b$ of $\beta$. A popular statistic for testing $H_0$ is via the $F$-statistic

$$T = \frac{SSE(\hat{\beta}) - SSE(\hat{\beta}_r)}{q\hat{\sigma}^2},$$

(3)

where $\hat{\sigma}^2$ is the LS estimator of $\sigma^2$ in the full model (1). Toro–Vizcarrondo and Wallace (1968) show that $T$ has a $F$ distribution with degrees of freedom $q$ and $(n - (p + q))$ and non-centrality parameter (in the notation of Kotz and Johnsson, 1970),

$$\lambda = n \frac{d_n(\beta_2)}{\sigma^2}, \quad d_n(\beta_2) = \frac{1}{n} \beta_2^t X_2^t M_{X_1} X_2 \beta_2,$$

where $M_{X_1} = I_n - P_{X_1}$, $P_{X_1} = X_1(X_1^t X_1)^{-1} X_1^t$ and $I_n$ is the identity matrix of dimension $n$. Thus, under $H_0$, $T$ is central $F$ distributed with $q$ and $(n - (p + q))$ degrees of freedom.

For many purposes it is not adequate to base a decision for or against the sub-model (2) on testing the hypothesis $H_0$. For example, Toro–Vizcarrondo and Wallace (1968) pointed out that the estimator $\hat{\beta}_r$ can have a smaller MSE (mean square error) than $\hat{\beta}$, even if the model (2) is incorrect. Therefore they suggested to test the hypothesis

$$H_{MSE} : MSE(\hat{\beta}_r) \leq MSE(\hat{\beta}),$$

where $MSE(b) = E((b - \beta)(b - \beta)^t)$, and $MSE(\hat{\beta}_r) \leq MSE(\hat{\beta})$ means that $MSE(\hat{\beta}) - MSE(\hat{\beta}_r)$ is positive semidefinite. Toro–Vizcarrondo and Wallace (1968) showed that the hypothesis $H_{MSE}$ is equivalent to $\lambda \leq 1$, which they used to construct a uniformly most powerful test for $H_{MSE}$ based on $T$. Hypotheses related to $H_{MSE}$ were investigated by Wallace (1972) and by Yancey et al. (1973).

The hypothesis $H_{MSE}$ still has some drawbacks. Instead of comparing models, it compares the performance of certain estimators. This is a somewhat arbitrary choice since there are other estimators (e.g. the ridge estimator, cf. Farbrother, 1975), which have smaller MSE than the LS estimator. Further, and more importantly, even if the hypothesis $H_{MSE}$ (or $H_0$) cannot be rejected with a large p-value, this does not imply that the sub-model (2) is actually true. Therefore, we suggest to test a hypothesis which focuses on validating the sub-model (2). A related approach to validating parametric functional forms of regression models (against nonparametric alternatives) was suggested by Dette and Munk (1998).

To this end, note that $d_n(\beta_2)$ is the normalized length (with factor $n^{-1}$) of the $n$ vector $X_2 \beta_2$, when projected onto the orthogonal complement of the space spanned by the columns of $X_1$. Thus it provides a natural measure of distance between the restricted model (2) and the full model (1), and we propose to validate sub-model (2) by testing the hypothesis that

$$H_{\Delta,n} : d_n(\beta_2) > \Delta \quad \text{against} \quad K_{\Delta,n} : d_n(\beta_2) \leq \Delta,$$

for some $\Delta > 0$. Under normality we have that $H_{\Delta,n}$ is equivalent to $H_{\lambda,n} : \lambda > n\Delta/\sigma^2$. Since $\sigma^2$ is unknown we cannot construct even under normality an exact test of $H_{\Delta,n}$. Therefore we give a condition under which $d_n(\beta_2)$ converges as $n \to \infty$, say to $d(\beta_2)$, and consider testing $H_{\Delta} : d(\beta_2) > \Delta$ against $K_{\Delta} : d(\beta_2) \leq \Delta$. For this testing problem we will construct an asymptotic test which does not require normality of the errors.
3 An asymptotic test

In order to formulate an asymptotic version of the hypotheses $H_{\Delta,n}$, we need the following assumption.

**Assumption 1.** The regressors $X$ are non-random and we have $X^t X / n \to G$ as $n \to \infty$, where $G \in \mathbb{R}^{(p+q) \times (p+q)}$ is a symmetric positive definite matrix.

Split $G$ into blocks as follows

$$G = \begin{pmatrix} G_{11} & G_{12} \\ G_{21} & G_{22} \end{pmatrix}$$

Then the asymptotic version of the distance $d_n(\beta)$ is defined as

$$d(\beta_2) = \beta_2^t (G_{22} - G_{21} G_{11}^{-1} G_{12}) \beta_2,$$

and the corresponding version of $H_{\Delta,n}$ as

$$H_\Delta : d(\beta_2) > \Delta \quad \text{against} \quad K_\Delta : d(\beta_2) \leq \Delta.$$  

In fact, under assumption 1 one can show that $d_n(\beta_2) \to d(\beta_2)$ as $n \to \infty$. Note that the matrix $G_{22} - G_{21} G_{11}^{-1} G_{12}$, used in the definition of $d(\beta_2)$, is the Schur complement of the block matrix $G_{11}$ and is positive definite since $G$ is assumed to be positive definite. Let $P_X = X (X^t X)^{-1} X^t$ and consider the test statistic

$$R_n = \frac{1}{n} (SSE(\hat{\beta}_n) - SSE(\hat{\beta})) = \frac{1}{n} Y^t (P_X - P_X) Y,$$

which estimates $d_n(\beta_2)$.

**Theorem 1.** Under assumptions 1 - 4 (cf. the appendix), if $d(\beta_2) > 0$ we have that

$$\sqrt{n} (R_n - d(\beta_2)) \xrightarrow{L} N(0, 4\sigma^2 d(\beta_2)) \quad \text{as} \quad n \to \infty.$$ 

The proof of theorem 1 is given in the appendix. Using theorem 1, we construct an asymptotic test for $H_\Delta$ as follows. Given $\Delta > 0$, reject $H_\Delta$ with level $\alpha > 0$ if

$$\sqrt{n} \frac{R_n - \Delta}{2\hat{\sigma}\sqrt{n}} \leq u_\alpha,$$

where $u_\alpha$ denotes the $\alpha$-quantile of the standard normal distribution. Thus, the choice of $\Delta$ is evidently critical for the test decision. Note that for a given level $\alpha$ (e.g. $\alpha = 0.05$), one can determine the threshold $\Delta_{\text{crit,} \alpha}$ for which $H_{\Delta_{\text{crit,} \alpha}}$ can be rejected at level $\alpha$, while $H_\Delta$ cannot be rejected for $\Delta < \Delta_{\text{crit,} \alpha}$:

$$\Delta_{\text{crit,} \alpha} = \left( (R_n + \hat{\sigma}^2 u_\alpha^2 / n)^{1/2} - \hat{\sigma} u_\alpha / \sqrt{n} \right)^2.$$
Now \( \Delta \) is a threshold for \( d(\beta) \), the limit of the distance \( d_n(\beta) \), which as mentioned above measures the normalized (with factor \( n^{-1} \)) distance of the projected vector \( X_2\beta \). Therefore, we suggest to normalize \( \Delta_{\text{crit},\alpha} \) by an estimate of the total normalized length \( \beta'X'X\beta/n \):

\[
D_{\alpha,n} = \frac{\Delta_{\text{crit},\alpha}}{\beta'X'X\beta/n}
\]

The quantity \( D_{\alpha,n} \) can be nicely interpreted as the estimated maximal relative error one makes (with level \( \alpha \)) if one uses sub-model (2) instead of the full model (1). In fact, one has \( D_{\alpha,n} \to d(\beta^0)/(\beta^0G\beta) \) in probability as \( n \to \infty \). Model validation now proceeds in terms of \( D_{\alpha,n} \): If \( D_{\alpha,n} \) is less than some fixed value which we allow as maximal relative error (say 0.1 or 0.05), then we use the smaller sub-model.

4 Simulation study

In this section we conduct a small simulation study in which we investigate the performance of our method for model selection as compared to the AIC, the BIC and the t-test. Here, for the computation of the AIC and the BIC we use the residual sum of squares (with appropriate penalty term), in spite of the fact that for non-normally distributed errors, it is not the maximized log-likelihood function. This is because we do not want to assume a specific distributional structure of the errors to be known in advance.

We use a linear regression model with 7 covariates and the intercept, where the covariates are drawn uniformly from \([-1,1]\). The vector of true regressions coefficients is chosen as

\[
\beta = (\beta_0, \beta_1, \beta_2, \beta_3, \beta_4, \beta_5, \beta_6, \beta_7)' = (2, 2, 0.1, 0.1, 0.1, 2, 0.1, 2)'.
\]

Evidently, the relevant covariates that we want to identify are the 1st, 5th and 7th covariate and the intercept (which corresponds to \( \beta_0 \) and in the following is assumed to be contained in all submodels).

The distinct methods are applied in a backward selection procedure. More specifically, consider the method suggested in section 3. In the first step, we compute \( D_{\alpha,n} \) with \( \alpha = 0.05 \) for all submodels of the full model with 6 covariates and the intercept. Let \( M_1 \) be the submodel with minimal \( D_{\alpha,n} \), denoted \( D_{1,\alpha,n} \). If \( D_{1,\alpha,n} \) is smaller than some threshold, which we take as 0.05, then we continue with model \( M_1 \), otherwise we select the full model. In the next step, consider all submodels of \( M_1 \) with 5 covariates and the intercept, and compute \( D_{\alpha,n} \) for all these models, relative to \( M_1 \) (i.e. the denominator is computed in model \( M_1 \)). Let \( M_2 \) denote the submodel with minimal \( D_{\alpha,n} \), denoted \( D_{2,\alpha,n} \). If \( D_{2,\alpha,n} \) is smaller than 0.05, then we continue with model \( M_2 \), otherwise we select \( M_1 \). We proceed in this way until a model is selected or all covariates are discarded (and only the intercept remains). The other methods are applied in a similar fashion. For the information criteria, we iteratively discard covariates as long as the AIC and the BIC decreases in a submodel, and continue with the submodel with the smallest AIC or BIC. Finally, for the t-test, in the first step for

</tbody>
</table>

Each submodel with 6 covariates and the intercept we compute the p-value for the t-test that the coefficient \( \beta_i \) of the missing covariate is zero. Let \( M_1 \) be the submodel for which the corresponding t-test has maximal p-value \( p_1 \). If \( p_1 > 0.05 \), we continue with model \( M_1 \), otherwise we choose the full model. In the next step for each submodel of \( M_1 \) with 5 covariates and the intercept we compute the p-value for the t-test that the coefficient \( \beta_j \) of the covariate missing from \( M_1 \) is zero. If \( M_2 \) denotes the submodel for which the corresponding t-test has maximal p-value \( p_2 \), we continue with \( M_2 \) if \( p_2 > 0.05 \), otherwise we choose \( M_1 \). We refer to Miller (2002) for other selection methods than backward selection. For example, one may modify our method in order to construct a forward selection procedure by considering \( K_\Delta \) as the null hypothesis and \( H_\Delta \) as the alternative.

The simulation is conducted as follows. After drawing the covariates once, these remain fixed subsequently, and we generate responses on model (1) for 1000 iterations, and for sample sizes \( n = 100 \) and \( n = 200 \). In each case, we apply the backward selection procedures described above.

Further, we use two kinds of error distributions, namely a t distribution with 6 degrees of freedom and an exponential distribution. For each distribution we consider two distinct scaling parameters. For the t distribution, we use scaling factors of \( \tau = 1 \) and of \( \tau = \sqrt{1.33} \), which gives for the error variance 1.5 for \( \tau^2 = 1 \), and 1.995 for \( \tau^2 = 1.33 \), respectively. For the exponential distribution, we use \( \lambda = 1 \) and \( \lambda = 1/\sqrt{2} \), giving variances of 1 (\( \lambda = 1 \)) and 2 (\( \lambda = 1/\sqrt{2} \)). Further, we center the errors by their expectation. For the scaled t distribution with \( \tau = 1 \) (\( \tau = \sqrt{1.33} \)) we observe that 50% of the regression data have a signal to noise ratio (mean divided by standard error) larger than 1.65 (1.44). For exponentially distributed errors, the signal to noise ratio for 50% of the regression data with \( \lambda = 1 \) (\( \lambda = 1/\sqrt{2} \)) is larger than 2.17 (1.54).

Table 1 shows the results for one simulation with t distributed errors (with \( \tau = 1 \)) and \( n = 100 \). Since all methods depend monotonically on the statistic \( SSE(\hat{\beta}_i) - SSE(\hat{\beta}) \), they proceed in the same steps. The desired model appears in step 4, which is selected by all methods except for the AIC (which includes too many covariates). Tables 2 and 3 show, for scaled t distributed and exponentially distributed errors, respectively, how often among 1000 iterations the desired model was selected. Here different rows correspond to different random covariates, whereas within the rows these covariates are fixed.

For \( n = 100 \) and \( \tau = 1 \) or \( \lambda = 1 \) (yielding higher signal to noise ratios), the \( D_{a,n} \) method selects the desired model in more than 90% of the simulations, and for \( n = 200 \).
Table 2: Number of iterations in which the desired submodel consisting of $x_0, x_1, x_5, x_7$ is selected; errors are scaled t distributed with 6 df. For $D_{\alpha,n}$, we choose $\alpha = 0.05$ and the threshold value also equal to 0.05.

it does so almost always. In contrast, the BIC, the AIC and the t-test more often select larger models. This is mainly due to the thresholding used for the $D_{\alpha,n}$. Only if the $D_{\alpha,n}$ increases significantly (namely becomes larger than 0.05) we stop the model selection procedure. Observing Table 1, for the first four covariates the values of AIC and BIC change little, although they might increase slightly, which leads to the choice of a larger model. A huge increase only occurs if the 5th covariate is discarded. Therefore, if one used a threshold (say 350 for the BIC), one would get similarly precise results as for the $D_{\alpha,n}$ method. However, for the $D_{\alpha,n}$ method such a threshold has a natural interpretation as maximal relative error, whereas there is no such interpretation for the values of the BIC and the AIC. The t-test also uses a threshold, i.e. for the p-value. If we chose it much smaller (e.g. 0.005) we would also recover the relevant model almost always. However, such a high precision is unnatural for a sample size $n = 100$ or $n = 200$. Furthermore, if we do not reject with a p-value of 0.04, this does not say anything about how good the smaller model still is.

Finally, we investigate the quality of the normal approximation in Theorem 1. We have to consider a testing situation where the hypothesis $H_{\Delta=0.05}$ is true, and where the complete model is included under this hypothesis. Therefore, we test the complete model against the model where the covariate $x_7$ is excluded, and simulate the statistic $R_n$ 10000 times for sample sizes $n = 30, 50$ and 100 and centered exponentially distributed errors. For visualization in Figure 1 we use P-P plots, which show for each $\alpha \in [0, 1]$ the empirical probability of the event $\{\sqrt{n}[R_n - d_n(\beta_2)] \leq Q_\alpha\}$, where $Q_\alpha$ is the $\alpha$-quantile of the asymptotic normal distribution with consistently estimated variance. From the top row of Figure 1 we see that the asymptotic approximation is quite good already for rather small sample sizes. Note that for the test decision (4), the approximation for small $\alpha$’s is relevant, which can be assessed using the bottom row.

Summarizing the results of the simulation study we see that the performance of our method depends to some extend on the signal to noise ratio, especially for small sample sizes. In such cases ($n = 100$), it performs well for signal to noise ratios larger than 1.5. For large $n$, the dependence on the signal to noise ratio becomes weaker.

5 College spending data

To illustrate our method in a practical application we analyze the college spending data from U.S. News and World Report 1994 College Guide. The complete data can be found in Dielman (1996) and its short description is given in Table 4. The variable of interest is educational spending per full-time equivalent (SPEND) given for 147 US colleges. A simple explorative data analysis shows that there is a presence of variance heterogeneity and a log transformation of the response SPEND is needed. Further, for numerical stability, all variables including the response SPEND are centered and normalized by their sample mean and sample standard deviation. In Table 5, the results of a backward selection procedure for the $D_{\alpha,n}$ method, the BIC, AIC and the t-test, applied to the college spending data, are given. Here, we always keep the intercept in the submodels. Further, for the $D_{\alpha,n}$ we
Figure 1: P-P plots for $\sqrt{n}[R_n - d_n(\beta_2)]$ based on 10000 replications (top row $\alpha \in (0, 1)$, bottom row $\alpha \in (0, 0.1)$)

use a level of $\alpha = 0.05$ and a threshold of 0.05.
The BIC, the t-test and the $D_{a,n}$ method choose a submodel consisting of the three covariates SAT, TOP10 and RATIO, and only the AIC prefers a model with 4 covariates. This is in agreement with the simulation results in Section 4. Let us stress that in contrast to the BIC and the t-test (with a p-value of 0.89 in the final step), the $D_{a,n}$-method allows for a clear interpretation of the quality of the resulting submodel, namely that the maximal relative error we make when using this smaller submodel is less than 0.05, with probability 0.95.

6 Conclusion

In this paper we introduced a new method for testing linear restrictions in linear regression models. It allows to test the validity of the linear restriction, up to a specified approximation error and with a specified error probability. The method can also be used to estimate a quantity $D_{a,n}$, which can be interpreted as the estimated maximal relative error (with level $\alpha$) that one makes when using the smaller submodel. This quantity $D_{a,n}$ can be conveniently used for model-selection purposes. In contrast to classical model selection criteria such as the AIC and the BIC, the value $D_{a,n}$ has a clear interpretation (as maximal relative error), and therefore allows for model selection strategies based on a threshold value for $D_{a,n}$. As illustrated in a simulation study as well as a real data example, this might lead to good results in the model selection process.

**Appendix**

**Assumption 2.** The errors $\epsilon_1, \ldots, \epsilon_n$ are i.i.d. with $E(\epsilon_i) = 0$, $Var(\epsilon_i) = \sigma^2$ and $E(\epsilon_i^4) < \infty$.

**Assumption 3.** We have that

$$\sqrt{n}(n^{-1}X^tX - G) \to 0. \quad (5)$$

**Assumption 4.** The entries of the covariate matrix $X_2$ lie in a compact set $K \subset \mathbb{R}$ for all $n$.

Note that from Assumptions 3 and 4 it follows that

$$\sqrt{n}\left[\left(\frac{1}{n}X^tX\right)^{-1} - G^{-1}\right] \to 0 \quad (6)$$

since taking the inverse of a matrix is a Lipschitz continuous mapping on compact sets.

**Proof of Theorem 1.** First note that from (5) and (6) it follows that

$$\sqrt{n}(d_n(\beta_2) - d(\beta_2)) \to 0.$$
Since by assumption, $d(\beta_2) > 0$, $d_n(\beta_2)$ will be bounded away from 0 and we get
\[
\sqrt{n} \frac{R_n - d(\beta_2)}{2\sigma \sqrt{d_n(\beta_2)}} = \sqrt{n} \frac{\frac{1}{n} Y^t (P_X - P_{X_1}) Y - d_n(\beta_2)}{2\sigma \sqrt{d_n(\beta_2)}} + o(1) \tag{7}
\]
\[
\text{From Theil (1973), p. 146,}
\]
\[
P_X - P_{X_1} = M_{X_1} X_2 (X_2^t M_{X_1} X_2)^{-1} X_2 M_{X_1} =: Q,
\]
where $M_{X_1} = I_n - P_{X_1}$. The matrix $Q$ is symmetric and idempotent and satisfies $Q X_1 = 0$. Therefore
\[
\frac{1}{n} Y^t (P_X - P_{X_1}) Y = \frac{1}{n} \epsilon^t Q \epsilon + 2 \frac{1}{n} \beta_2^t X_2^t Q \epsilon + \frac{1}{n} \beta_2^t X_2^t Q X_2 \beta_2
\]
\[
= S_1 + S_2 + d_n(\beta_2). \tag{8}
\]
Now $ES_1 = tr \ Q/n \leq q/n$, and from Seber and Lee (2003, Theorem 1.6),
\[
Var (S_1) = \frac{1}{n^2} \left[ (\mu_4 - 3\sigma^4) h^t h + 2\sigma^4 tr(Q) \right],
\]
where $\mu_4 = E(\epsilon_1^4)$ and $h$ is the vector of diagonal elements of the matrix $Q$, for which $h^t h \leq q^2$. Thus
\[
S_1 = O_P(|ES_1| + |S_1 - ES_1|) = O_P(n^{-1}).
\]
Furthermore, $ES_2 = 0$ and
\[
Var (S_2) = \frac{4}{n} \cdot \sigma^2 d_n(\beta_2) \sim \frac{4}{n} \cdot \sigma^2 d(\beta_2),
\]
and therefore the term $S_2$ dominates the asymptotics in (8). It remains to show asymptotic normality of $S_2$. To this end we check the Lyapounov condition
\[
\frac{1}{n^{3/2}} \sum_{i=1}^n E |b_i \xi_i|^3 = \frac{E|\xi_1|^3}{n^{3/2}} \sum_{i=1}^n |b_i|^3 \to 0 \quad \text{as} \quad n \to \infty,
\]
where $b := 2\beta_2^t X_2^t Q = (b_1, \ldots, b_n)$. It will be enough to show that the entries $b_i$ are uniformly bounded. To this end, from assumption 4,
\[
\max_{i=1, \ldots, n} |b_i| = \max_{i=1, \ldots, n} |(Q X_2 \beta_2)_i| \\
\leq \max_{i=1, \ldots, n} \left\{ \sum_{k=1}^n |[Q]_{ik} | \cdot |(X_2 \beta_2)_k| \right\} \\
\leq C \max_{i=1, \ldots, n} \left\{ \sum_{k=1}^n |[Q]_{ik} | \right\},
\]
13
where $C > 0$ and $[\cdot]_{ik}$ denotes the $(i,k)$-th entry of the corresponding matrix. Since $Q$ is symmetric and positive semi-definite, $|[Q]_{ik}| \leq (Q_{ii} + Q_{kk})/2$, and thus

\[
m\max_{i=1,\ldots,n} |b_i| \quad \leq \quad C \max_{i=1,\ldots,n} \left\{ \frac{1}{2} \sum_{k=1}^{n} |Q|_{ii} + |Q|_{kk} \right\} \\
= \quad C \max_{i=1,\ldots,n} \left\{ \frac{1}{2} |Q|_{ii} + \frac{1}{2} \text{tr}(Q) \right\} \\
\leq \quad C \cdot q.
\]

This finishes the proof of theorem 1. \qed
