Abstract

Background. A relevant number of patients receive triple therapy with clopidogrel, aspirin, and oral anticoagulation. Clopidogrel’s efficacy on ADP induced platelet function may be influenced by concomitant antithrombotic therapies. Data regarding the effect of dabigatran on platelet function is limited to in vitro studies and healthy individuals. Methods. The "Dabi-ADP-1" and "Dabi-ADP-2" trials randomized patients with atrial fibrillation to either dabigatran or phenprocoumon for a 2-week period. In Dabi-ADP-1 (n = 70) patients with clopidogrel therapy were excluded and in Dabi-ADP-2 (n = 46) patients had to be treated concomitantly with clopidogrel. The primary endpoint was ADP-induced platelet aggregation between dabigatran and phenprocoumon at 14 days. Secondary endpoints were ADPtest HS-, TRAP-, and COL-induced platelet aggregation.

Results. There was no significant difference regarding the primary endpoint between both groups in either trial (Dabi-ADP-1: Dabigatran: 846 [650–983] AU × min versus phenprocoumon: 839 [666–1039] AU × min, P = 0.90 and Dabi-ADP-2: 326 [268–462] versus 350 [214–535], P = 0.70) or regarding the secondary endpoints, ADPtest HS-, TRAP-, and COL-induced platelet aggregation.

Conclusion. Dabigatran as compared to phenprocoumon has no impact on ADP-induced platelet aggregation in atrial fibrillation patients neither with nor without concomitant clopidogrel therapy.

1. Introduction

Dabigatran is at least as effective as vitamin K antagonists in the prevention of stroke and systemic embolism in patients with atrial fibrillation [1]. Dabigatran etexilate (Pradaxa) is an oral prodrug that is converted by serum esterases to dabigatran, a potent, direct, competitive inhibitor of thrombin. Thrombin has multiple roles in hemostasis. It converts fibrinogen to fibrin which is necessary to form the fibrous matrix of blood clots and it also has a direct action on cells [2]. Thrombin has an impact on shape and vascular permeability of vascular endothelium and is the most potent agonist for platelet activation and aggregation [2]. By inhibiting thrombin, platelet signaling pathways are also blocked and therefore platelet function may be affected.

Data regarding the effect of dabigatran on platelet function is limited to in vitro studies [3–5] and studies in healthy individuals of modest size [6] and has so far not been tested in real life patients.

Triple therapy, the combination of aspirin, clopidogrel, and oral anticoagulation, is necessary in patients with coronary stent implantation who also have atrial fibrillation to reduce ischemic events [7]. With the advent of the direct oral anticoagulants (DOAC), substances such as dabigatran...
etexilate are also given concomitantly with clopidogrel [8]. Platelet function testing is more and more emerging in the clinical routine because it has been shown that in patients who are treated with dual antiplatelet therapy (DAT) with aspirin and clopidogrel, both low and high on-treatment platelet reactivity (HPR) are associated with adverse clinical events [9]. One factor that may predispose to HPR is the patients’ comedication that may interfere with clopidogrel metabolization. In fact, there is some evidence that traditional anticoagulants such as the vitamin K antagonist phenprocoumon attenuate the antiplatelet effects of clopidogrel [10].

In the setting of concomitant clopidogrel therapy, it was already demonstrated that the parenteral direct thrombin inhibitor bivalirudin was able to further inhibit ADP induced platelet aggregation [11, 12]. Whether this is due to a direct interaction with the platelets or has an impact on clopidogrel metabolization is unclear. The oral direct thrombin inhibitor dabigatran is currently challenging the role of vitamin K antagonists in patients with atrial fibrillation and in those treated with triple therapy [8]. Therefore evaluating its role on platelet function and clopidogrel metabolization in real life patients is imperative. It is therefore our aim to evaluate whether dabigatran as compared to phenprocoumon alters ADP mediated platelet signaling pathway in clopidogrel naive patients or in patients concomitantly treated with clopidogrel. We therefore initiated two randomized trials to study the impact of dabigatran as compared to phenprocoumon (i) on ADP induced platelet aggregation in patients with atrial fibrillation (Dabi-ADP-1) and (ii) on clopidogrel mediated ADP induced platelet aggregation in patients with atrial fibrillation who are concomitantly treated with clopidogrel (Dabi-ADP-2).

2. Methods

2.1. Study Population. The “Impact of DAB1gatran and phenprocoumon on the ADP induced platelet aggregation in patients with atrial fibrillation” (DABI ADP 1) study and the “Impact of DAB1gatran and phenprocoumon on the clopidogrel mediated ADP induced platelet aggregation in patients with atrial fibrillation” (Dabi-ADP-2) study were two single centre randomized open label trials designed to compare the impact of dabigatran etexilate (Pradaxa) versus the vitamin K antagonist phenprocoumon on platelet function (ClinicalTrials.gov identifiers: NCT01339819 and NCT01352702). Patients were enrolled at the Deutsches Herzzentrum Munich between April 2011 and February 2013.

Both trials shared the same inclusion and exclusion criteria with the main difference that in Dabi-ADP-1 patients with clopidogrel therapy were excluded and in Dabi-ADP-2 had to be treated concomitantly with clopidogrel. Patients were eligible if they were 18 years of age, if they had atrial fibrillation with an indication for oral anticoagulation, and if written informed consent by the patient or her/his legally authorized representative for participation in the study was obtained. Exclusion criteria included patients with a recent thromboembolic event (defined as severe disabling stroke in the last 6 months or any stroke in the last 14 days) or a high thromboembolic risk such as a history of mechanical valve, pulmonary embolism, deep vein thrombosis, or LV thrombus. In addition, patients with a contraindication for oral anticoagulation, active bleeding or high bleeding risk, cardiogenic shock, severe renal insufficiency (Creatinine Clearance < 30 mL/min), or moderate or severe hepatic impairment (Child-Pugh class B or C) were excluded. The studies were conducted in accordance with the provisions of the Declaration of Helsinki and with the International Conference on Harmonization Good Clinical Practices. The trial protocols were approved by the institutional ethics committee responsible for the Deutsches Herzzentrum Munich (Germany) and the Bundesinstitut für Arzneimittel und Medizinprodukte (BfArM, Germany).

2.2. Study Protocol. Patients who met all of the inclusion criteria and none of the exclusion criteria were randomized in the order that they qualify. Allocation to treatment was made by means of sealed envelopes containing a computer-generated sequence. Patients were randomized according to a 1×1 factorial design to a dabigatran versus a phenprocoumon therapy for 2 weeks. Time zero was defined as the time of randomization. Patients were considered enrolled in the study and eligible for the final intention to treat analysis at the time of randomization. Commercially available drugs were given according to the protocol.

Oral anticoagulation with phenprocoumon or dabigatran was given on the day of randomization and was administered orally at the dosage recommended by current guidelines [13, 14]. Phenprocoumon was given with a target INR of 2.0–3.0 and dabigatran was administered at a dosage of 110 mg or 150 mg twice daily. Study drugs were provided by the sponsor (Deutsches Herzzentrum Munich). Other cardiac medications were given according to the judgment of the patients’ physician (e.g., ASA, ß-blockers, ACE-inhibitors, statins, proton pump inhibitors, etc.). Patients were scheduled for an outpatient visit at 14 days after randomization for clinical follow-up and laboratory testing (see below).

2.3. Laboratory Testing. Whole blood for platelet function testing on the Multiplate analyzer (Roche Diagnostics, Basel, Switzerland) was obtained from the cubical vein. Blood was placed in 4.5 mL plastic tubes containing the anticoagulant lepirudin (25 µg/mL; Refludan, Dynabyte, Munich, Germany). Platelet aggregation was assessed with multiple electrode aggregation (MEA) using an impedance aggregometer (Multiplate analyzer). ADP (6.4 µmol/L), ADPtest HS (6.4 µmol/L ADP in the presence of 9.4 nmol/L prostaglandin E1, TRAP-6 (32 µmol/L), and Collagen (3.2 µg/mL collagen (COLtest)) served as agonists. Details of this method have been reported previously [15, 16]. Aggregation measured on the Multiplate device is quantified as area under the curve of aggregation units (AU) (area under the curve = AU × min).

All material used for platelet function testing was obtained from the manufacturer.

2.4. Study Endpoints and Definitions. The primary endpoint of both studies was the ADP induced platelet aggregation in patients treated with dabigatran versus phenprocoumon.
treatment at 14 days. ADP was chosen as primary endpoint because there is a multitude of studies that have linked alterations in the ADP value associated with antithrombotic therapy with clinical events [9].

The secondary endpoints were ADPtest HS, TRAP, and COL induced platelet aggregation in patients treated with dabigatran versus patients with phenprocoumon treatment at 14 days.

Patients were further monitored throughout the two-week study period for the occurrence of adverse events such as death, stroke, myocardial infarction (MI) according to TIMI criteria [17], stent thrombosis, TIMI major, or TIMI minor bleeding [17]. The diagnosis of ischemic or haemorrhagic stroke required confirmation by computed tomography or magnetic resonance imaging of the head. Adjudication of bleeding events according to BARC criteria [18] was done in a retrospective manner.

2.5. Follow-Up. Detailed information regarding the occurrence of adverse events was obtained in this population during follow-up at 14 days in the outpatient clinic. Patients who could not come to the hospital were interviewed by phone. Those with cardiac complaints underwent a complete clinical, electrocardiographic, and laboratory check-up. General practitioners, referring cardiologists, patients, or their relatives were contacted for additional information if necessary.

Relevant data were collected from source documents and prospectively entered into a computerized database by specialized personnel of the data coordinating Intracoronary Stenting and Antithrombotic Research (ISAR) center.

2.6. Statistical Methods. There is some evidence that the parenteral direct thrombin inhibitor bivalirudin results in further inhibition of ADP induced platelet aggregation [12] while phenprocoumon attenuates clopidogrel mediated ADP aggregation [10]. Sample size calculation was therefore based on the assumption that administration of dabigatran as compared to phenprocoumon results in a 25% absolute decrease of maximal ADP. Choosing a power of 80% and a two-sided $\alpha$ value of 0.05 a sample size of at least 29 per group was required. To compensate for losses to follow-up, each study was designed to enroll a total of 70 patients (35 per group).

In Dabi-ADP-2 a blinded interim review performed in February 2013 demonstrated that more than 1000 patients would need to be included to show a significant difference between groups. On the basis of these data, the steering committee decided to terminate Dabi-ADP-2 prematurely for futility.

A comparison of categorical variables, expressed as counts (percentages), was performed using the Fisher exact or the $\chi^2$ test, as appropriate. Continuous variables were expressed as means ($\pm$SD) and compared with the unpaired, 2-sided Student’s t-test if normally distributed; otherwise, they were expressed as medians (25th–75th percentile) and statistically analysed by the Wilcoxon rank-sum test.

A $P$ value <0.05 was considered to indicate statistical significance. All statistical analyses were performed with the software R (version 2.15.0; The R Foundation for Statistical Computing).

3. Results

3.1. Populations. In Dabi-ADP-1, 70 patients were enrolled and randomized to receive dabigatran ($n = 35$) or phenprocoumon ($n = 35$). There was no significant difference in terms of baseline patient characteristics (Table 1). Median INR levels (interquartile range) at baseline were 1.1 (1.0–1.1) in the dabigatran group and 1.1 (1.1–1.2) in the phenprocoumon group. According to intention to treat analysis the primary and secondary endpoints could be analyzed in 30 patients in the dabigatran group and 32 patients in the phenprocoumon group (Figure 1).

In Dabi-ADP-2, 46 patients concomitantly treated with clopidogrel were enrolled and randomized to receive dabigatran ($n = 22$) or phenprocoumon ($n = 24$). There was no significant difference in terms of baseline patient characteristics (Table 1). Median INR levels (interquartile range) at baseline were 1.2 (1.1–1.2) in the dabigatran group and 1.2 (1.1–1.4) in the phenprocoumon group. According to intention to treat analysis there was no significant difference regarding the primary and secondary endpoints could be analyzed in 20 patients in the dabigatran group and 20 patients in the phenprocoumon group (Figure 2).

3.2. Platelet Function Tests. There was no significant difference regarding the primary endpoint of ADP induced platelet function between patients treated with dabigatran as compared to patients with phenprocoumon treatment in either trial at 14 days (Dabi-ADP-1: 846 [650–983] AU $\times$ min versus 839 [666–1039] AU $\times$ min, $P = 0.90$ (Figure 3) and Dabi-ADP-2: 326 [268–462] AU $\times$ min versus 350 [214–353] AU $\times$ min, $P = 0.70$ (Figure 4)). There was also no significant difference regarding the secondary endpoints ADPtest HS, TRAP, and COL in either trial (Figures 3 and 4). Median INR values at follow-up were 1.2 (1.1–1.3) in the dabigatran group and 2.6 (1.9–3.3) in the phenprocoumon group in Dabi-ADP1 and 1.2 (1.1–1.4) in the dabigatran group and 3.0 (1.9–4.4) in the phenprocoumon group in Dabi-ADP-2.

In Dabi-APD-1 there was one patient in the dabigatran group who was switched to phenprocoumon and two patients in the phenprocoumon group who were switched to either rivaroxaban or enoxaparin by their primary physician during the study period (Figure 1). We therefore also analyzed patients according to the treatment they received. In the as treated analysis there was no significant difference regarding ADP induced platelet aggregation between patients treated with dabigatran ($n = 29$, as treated analysis) as compared to patients with phenprocoumon treatment ($n = 31$, as treated analysis) (850 [658–988] AU $\times$ min versus 842 [653–1044] AU $\times$ min, $P = 0.94$). There was also no significant difference regarding the secondary endpoints ADPtest HS (646 [529–760] AU $\times$ min versus 652 [457–855] AU $\times$ min, $P = 0.96$), TRAP (1195 [1049–1428] AU $\times$ min versus 1192 [1001–1399] AU $\times$ min, $P = 0.57$), and COL (804 [682–981] AU $\times$ min versus 752 [670–874] AU $\times$ min, $P = 0.42$).

3.3. Safety. In the phenprocoumon group of Dabi-ADP-2 there was one patient who suffered from stent thrombosis on day 13 due to clopidogrel discontinuation. In this patient ADP induced platelet aggregation was 1417 AU × min when he presented with STEMI to our emergency department. After clopidogrel loading and PCI of the culprit vessel he could be discharged and ADP values on follow-up under treatment with aspirin, clopidogrel, and phenprocoumon were 307 AU × min.

In both trials, no patient suffered from death, stroke, or TIMI minor or TIMI major bleeding during the follow-up period. The number of BARC Types 1 and 2 bleeding was low. In Dabi-ADP-1, there was one BARC Type 1 bleeding and 3 BARC Type 2 bleeding in the dabigatran group and none
in the phenprocoumon group. In Dabi-ADP-2, one BARC Type 1 bleeding occurred in the dabigatran group and 2 in the phenprocoumon group.

4. Discussion

The main finding of our two randomized trials is that dabigatran as compared to phenprocoumon has no impact on ADP induced platelet aggregation in atrial fibrillation patients neither with nor without concomitant clopidogrel therapy. Furthermore there were no significant differences regarding the other mediators of platelet aggregation such as TRAP or collagen.

The hemostatic process is a dynamic, highly interwoven array of multiple processes [19] and antithrombotic agents inhibit specific steps in the coagulation cascade or in platelet aggregation. There have been some antithrombotic substances in the past, however, which have shown to induce a prothrombotic state through modification of pathways which differ from those who are primarily targeted, with the consequence of increasing adverse clinical events [20].
In our current Dabi-ADP-1 trial in patients with atrial fibrillation with no concomitant clopidogrel therapy, we could show that the direct thrombin inhibitor dabigatran has no impact on ADP, ADPtest HS, TRAP, and COL induced platelet aggregation as compared to phenprocoumon. As it is known, that phenprocoumon itself does not alter ADP induced platelet aggregation in patients solely treated with the vitamin K antagonist [21], our data suggests that dabigatran has no impact on ADP induced platelet function.

Our results are in line with the finding of former in vitro studies which could demonstrate no impact of dabigatran on ADP induced platelet aggregation in platelet rich plasma [3, 5]. Furthermore the values obtained for platelet function in our population treated with either dabigatran or phenprocoumon are similar to the normal reference intervals which were established in 117 healthy individuals [22].

Clinically, there is still an ongoing discussion regarding a prothrombotic effect of dabigatran. In the large multicenter RE-LY trial [1], concerns were raised that the rates of myocardial infarction were significantly increased in both tested dosages, which was debilitated after publication of a subsequent analysis of the RE-LY trial, where also silent MI
were included [23, 24]. In contrast to this data, several meta-
alysis of randomized trials with dabigatran came to the
conclusion that dabigatran is associated with an increased
risk of MI or ACS in a broad spectrum of patients [25–27].
The underlying pathological mechanism for this observation
is still unknown.

Clopidogrel’s efficacy may be hampered by genetic factors
associated with clopidogrel metabolism as well as nongenetic
factors such as patients’ characteristics, comorbidities, and
comedication [28]. One important example is the coumarin
derivative phenprocoumon which is known to effectively
reduce coagulation parameters but does not alter ADP
induced platelet aggregation in patients solely treated with
the vitamin K antagonist [21]. It is of interest however
that concomitant treatment of phenprocoumon with DAT
significantly attenuated the antiplatelet effects of clopidogrel
in a previous study [10]. This is thought to be induced by a
drug-drug interaction at the level of hepatic CYP
metabolization, leading to a significant alteration of the
vivo biotransformation of clopidogrel into its active thiol
metabolite.

On the other hand, the parenteral direct thrombin
inhibitor bivalirudin, as compared to unfractionated heparin,
was able to further inhibit clopidogrel mediated ADP induced
platelet aggregation [11, 12]. We therefore hypothesized that
concomitant therapy with the oral direct thrombin inhibitor
dabigatran might show a similar effect on ADP induced
aggregation.

In fact, however, in our Dabi-ADP-2 trial in patients
with atrial fibrillation with concomitant clopidogrel and
aspirin therapy, we could show that the direct thrombin
inhibitor dabigatran has no impact on ADP, ADPtest HS,
TRAP, and COL induced platelet aggregation as compared to
phenprocoumon.

These findings may be explained in several ways: Both
phenprocoumon and dabigatran attenuate clopidogrel medi-
ated ADP induced platelet aggregation in the same way or
none of these substances have an impact on the platelet
function even in the setting of clopidogrel therapy.

Data regarding the influence of dabigatran on clopidogrel
mediated ADP induced platelet aggregation in patients is
limited. Recently one small study with 12 healthy male indi-
viduals has evaluated concomitant therapy with dabigatran
and clopidogrel on the pharmacokinetic and pharmacody-
namic effect of either agent [6]. It was shown that neither
ADP induced platelet aggregation nor the bioavailability of
either agent was significantly altered by the combined therapy
which is in line with our findings.

Our knowledge of the clinical role of new oral anticoag-
ulants as part of triple therapy is still limited. So far one post
hoc analysis of the RE-LY trial revealed that in the setting of
concomitant single or dual antiplatelet therapy, dabigatran is
associated with fewer bleeding events than warfarin [8] which
are promising results. In our randomized study, duration of
triple therapy with dabigatran was only 2 weeks and
the number of patients was low. This does not allow for a
meaningful assessment of the safety of this therapy. However,
it is known that most of the bleeding events occur early after
initiation of therapy [29]. We observed only few cases of Type
1 BARC bleeding.

**Study Limitations.** Limitations of Dabi-ADP-2 include
the small sample size and the premature termination of the study.
However results of our interim analysis implicated that in
Dabi-ADP-2 more than 1000 patients needed to be enrolled
and such a study is not feasible in such a patient population
receiving triple antithrombotic treatment.

Secondly, baseline platelet function tests at randomiza-
tion without any concomitant antithrombotic therapy were
not available in all patients. Therefore our trial does not
answer whether platelet function may have been affected
between baseline and at two weeks when the primary end-
point was assessed.

Thirdly, aggregation was not tested with other ago-
nists, such as thrombin-induced platelet aggregation, where
a concentration-dependent inhibition with dabigatran has
already been shown [3].

**5. Conclusion**

In conclusion, in these two randomized trials in patients
with atrial fibrillation we could not find an impact on
ADP induced platelet aggregation in patients treated with
dabigatran as compared to phenprocoumon neither with nor
without concomitant clopidogrel therapy.

**Clinical Perspective.** Traditional antithrombotic agents such
as vitamin K antagonists as well as clopidogrel are currently
challenged and will possibly be replaced by direct oral anti-
coagulants (apixaban, dabigatran, edoxaban, rivaroxaban)
and newer P2Y12 inhibitors (prasugrel, ticagrelor). In the
setting of triple therapy, choosing the right combination of
antiplatelet and anticoagulation therapy therefore becomes
more demanding as more options exist. Platelet function
studies are useful to evaluate potential medication interac-
tions which may attenuate their antithrombotic efficacy.

Clinically, limited data suggests that reductions in bleed-
ing complications in this population may be achieved with the
omission of aspirin [30], shorter therapy duration [31], or the
use of dabigatran [8]. Newer more potent P2Y12 blocker are
currently not recommended in the setting of triple therapy
[32] as they may increase bleeding without reducing ischemic
events [33]. Ongoing randomized studies such as PIONEER
AF-PCI (ClinicalTrials.gov identifier: NCT01830543) or RE-
DUAL PCI (ClinicalTrials.gov identifier: NCT02164864)
evaluate also the role of newer agents and will further help
to define the optimal treatment combination and duration in
this challenging population.

**Abbreviations**

AU: Aggregation units
DAT: Dual antiplatelet therapy
DOAC: Direct oral anticoagulants
HPR: High on-treatment platelet reactivity
MEA: Multiple electrode aggregation
MI: Myocardial infarction.
Ethical Approval
The studies were conducted in accordance with the ethical standards of the responsible committee on human experimentation (institutional and national), the provisions of the Declaration of Helsinki of 1975, revised 2000, and with the International Conference on Harmonization Good Clinical Practices and were in accordance.

Consent
Informed consent was obtained from all patients before being included in the study.

Disclosure
No animal studies were carried out by the author of this paper.

Conflict of Interests
Dr. Sibbing has been a consultant for Verum Diagnostica and Eli Lilly; receiving payment for lectures from Eli Lilly, Daiichi Sankyo, Astra Zeneca, CSL Behring, Roche Diagnostics, and Verum Diagnostica and achieved research grants from Roche Diagnostics. Dr. Mehilli indicates having received lecture fees from Daeichi Sankyo, Eli Lilly, Terumo, Abbott Vascular, and Biotronik. Dr. Saraoff reports having received lecture fees from Eli Lilly, Boehringer Ingelheim, Astra Zeneca, Roche Diagnostics, and Bayer Healthcare. Dr. Martischnig, Janina Pollak, Dr. Petzold, Dr. Fiedler, Dr. Mayer, Dr. Schulz-Schüpe, Dr. Massberg, and Dr. Kastrati declare that they have no conflict of interests relevant to this paper.
